In a democracy, political authority is based on the will of the people. From its origins in ancient Greece, the meaning of democracy has been contested and always questioned (Gallie, 1955–56). The history of democracy is the history of these debates, debates between democrats and their opponents and, no less vigorously and persistently, among the advocates of different sorts of democracy. Three overlapping sets of issues have dominated disagreements about democratic theory and practice. First and most obviously is the question of whom to include in the demos. If democracy means government by the people, who are the people? Everyone? All adults? All male adults? All male adults with property or education? Second is the matter of democracy's prerequisites. What rules, institutions, and values are necessary for democracy to succeed? Are correct procedures sufficient to ensure democratic government or does genuine democracy require a particular kind of society or culture? Is there one road to democracy or many? And finally, there is the issue of what might be called democracy's institutional scope. Is democracy primarily a political system of self-government or is it equally important, or equally necessary, in other aspects of life, such as the family, the workplace, and the schoolroom? In order for there to be a 'true' democracy must its principles and aspirations be realized throughout the social order?

Classical Models

The openness and complexity of democracy's history were already apparent in the fifth and fourth centuries BC when a number of Greek-speaking city states scattered across the eastern Mediterranean adopted various forms of popular self-government. From the beginning, there was an ambiguity in the meaning of demos which reflected the Greeks' uneasiness about democratic government. For democracy's admirers, the people's will confirmed legitimacy: decrees passed by popular assemblies often began with the words, 'the demos has decided.' But for democracy's critics, the people were the mob, unreliable and easily swayed by passion and self-interest. This is why Plato, in his famous attack on democracy in the eighth book of The Republic, argues that the excesses of democracy will inevitably lead to tyranny.

The ancient city's distinctive blend of religion and politics, the small scale of its public life, the superiority of the spoken over the written word in its political deliberations, and its emphasis on military service and war, reflected a distinctive set of historical conditions that would never be repeated. Nevertheless, the Greek experience continued to play a role in Europe's political imagination. Pericles's eloquent defense of Athenian democracy, recorded (or perhaps composed) by Thucydides in his history of the Peloponnesian War, was persistently cited as a statement of democratic virtue, just as Plato's and Aristotle's criticisms of democracy were used to underscore its dangers. Like the elements of classical buildings, which architects adapted over and over again to serve their own purposes, Greek ideas about democracy were repeatedly borrowed by European thinkers, who often imbedded them in structures quite distant from their original meaning and purpose.

There is no institutional continuity between ancient Greece and modern politics. The democratic practices that Pericles praised and Plato decried did not survive the destruction of the polis by internal discord and foreign enemies. To be sure, the Roman state based its legitimacy on the popular will: its armies fought in the name of 'The Senate and People of Rome.' But after the fall of the republic, first the substance and then the form of popular sovereignty disappeared from European history for almost a millennium. When they reappeared in the late middle ages, republican institutions were limited to relatively small entities, usually city-states, in which political power was in the hands of a narrow, exclusive elite. There were also a few self-governing rural communities in medieval and early modern Europe, but they were small and scattered. None of

these polities thought of itself as a democracy. The concept, revived with the rest of the Greek legacy in the late middle ages, was a matter for political theory and scholarly debates, not the everyday conduct of public affairs.

The Age of Democratic Revolution

The history of modern democratic practice begins with a series of political revolutions in the final decades of the eighteenth century. But before erupting into the realm of practical politics, democratic ideals were nourished by three currents of enlightenment thought: first was a new concept of the individual, whose identity was defined by his (and for a few, also her) own talents and desires, rather than his place in the social order; second was a new concept of equality, which accorded to each person (definitions of which varied greatly) the same rights and responsibilities; and finally there was a new concept of social and intellectual activity, which imagined a sphere of free competition among people, commodities, and ideas. Many, perhaps most, of the thinkers who formulated these ideas did not think of themselves as democrats; some of them expressly condemned democratic institutions in terms that Plato would have recognized. Nevertheless, enlightenment notions of individualism, equality, and society helped to undermine the ideological foundations of the old regime and to open the way for democracy's long and circuitous march to political power.

Among eighteenth-century political theorists the most significant for the history of democracy was Jean-Jacques Rousseau, whose ideas inspired the French Revolutionaries' assaults on the Old Regime and at the same time reflected democracy's deepest ambiguities. Rousseau is correctly regarded as a spokesman for individual liberty and, no less accurately, as the advocate of the individual's subordination to the 'general will.' He attempted to reconcile these two convictions with a program of education that aimed at freeing individuals from the corruptions of existing society and a program of political reform that was supposed to create institutions appropriate for the products of this education. The result would be a genuinely free society in which individuals want to choose what is best for them and for their community. Because this vision of total harmony between individual desire and social imperatives set a standard that no government could match, among Rousseau's legacies was the temptation to force people to be free, that is, to use political power to shape their desires to match the alleged needs of the community. At the same time Rousseau stated that democracy should never be established as a form of government, being 'a government of gods rather than men' (he preferred an aristocracy of the wise). Rousseau also declared that the sovereignty of the people that was the basis of every legitimate state could only ever be established in small states that were not commercial (he loved the Alpine cantons). Large states like France, he argued, were beyond the pale and could never be reformed. The fact that Rousseau inspired the popular aspects of events in France in the 1790s neatly captures the complicated nature of democracy and the irony that the philosopher in whose name the Revolution was conducted would himself have rejected the very idea of revolution in France.

The first step from democratic theory to democratic practice was taken on the far fringes of the European world, in North America, where the struggle for independence from colonial rule was carried out in the name of 'the people's' natural and inalienable right to self-government. Of course the new American democracy was qualified in a number of important ways: the demos excluded women, African-American slaves, and, in some places, men without sufficient property. Nevertheless, the creation of a republic in the new world established a regime whose institutions and legitimacy depended on the people's will.

The democratic experiment in America aroused widespread interest and some enthusiasm, but no imitators among enlightened Europeans. But when revolution engulfed France, Europe's greatest power and the recognized center of fashion and culture, its wider significance could not be ignored. In the summer of 1789, the French National Assembly solemnly proclaimed 'the rights of man and the citizen,' which promised social equality and political liberty. Sovereignty was now firmly rooted in the popular will: 'No body and no individual may exercise authority which does not emanate directly from the nation.' But who spoke for the nation? At each stage of the revolution there was a different answer to this question as power moved from the nation's elected representatives, to the mobilized people of Paris, to the Committee of Public Safety, to an elite of propertied men intent on restoring order, until it finally came to rest in the hands of an heroic young general, Napoleon Bonaparte. As the revolution moved from moderation to terror to reaction to military dictatorship to imperial monarchy, each successive regime invoked the nation, each claimed to rule in the people's name. Beyond France's borders, the revolution's friends and enemies shared one essential conviction: once the forces of democratic government had been unleashed, the world would never be the same.

For more than a century after the revolution was defeated, its historical memory lived on, a common source of inspiration and anxiety. People drew from the revolution's grand narrative the lessons appropriate for their political hopes and fears. To a democrat like Jules Michelet, the revolution was the truest expression of France's commitment to liberty, the most glorious chapter in the 'people's' struggle to realize their historical destiny. Reactionaries like Hippolyte Taine drew a different message from the revolution's course: popular sovereignty, he argued, will always lead first to anarchy, then despotism. But the revolution's most astute analyst was neither a democrat nor a reactionary: Alexis de Tocqueville saw it as part of a larger historical process through which the ideals and institutions of old-regime Europe were destroyed by the forces of social and political democracy that were deeply woven into the fabric of modern life. Like many of democracy's critics, Tocqueville feared it could easily lead to dictatorship; only in America was there a chance that democracy's true promise could be fulfilled (de Tocqueville, 1988).

The Nineteenth Century

In 1815, many Europeans hoped or feared that democracy had been defeated for ever. The monarchical principle seemed triumphant; republican institutions survived in Switzerland

and a precarious handful of city-states. Although monarchy remained the most common form of government in Europe for another century (France after 1870 was the most important exception), almost everywhere representative institutions gradually began to play an important role in public life. The right to vote, always the most obvious marker of democracy's progress, was granted to an increasing number of European males in the course of the century; political parties, interest groups, trade unions, and a variety of newspapers and other publications provided an infrastructure that supported political participation. By 1900, therefore, the distinction between monarchical and democratic governments, which conservative statesmen had struggled to maintain, was hopelessly blurred.

Every political movement had to come to terms with democratic pressures. During the first half of the century, most European liberals, who were the direct heirs of the Enlightenment's ideals of individualism, equality, and freedom, were suspicious of the masses – all the more so after the collapse of the French republic into terror and dictatorship. But in the course of the century, the left wing of the liberal movement was reconciled to democracy, supported universal suffrage (for men) and tried, with varying degrees of success, to win their share of the newly enfranchised voters. Conservatives, who had begun the century as democracy's most consistent enemies, were also unable to resist being pulled into the orbit of democratic politics. Following the example of the Emperor Napoleon III, who had consolidated his position with popular plebiscites after being elected president of France in 1848, conservative statesmen such as Bismarck in Germany and Disraeli in England, set out to use democratic means in support of conservative ends. No less remarkable than these 'Tory democrats' were the defenders of the Roman Catholic church, another of democracy's former enemies, who turned to electoral politics to defend their religious interests against the intrusions of the secular state. Here, too, we find evidence of the inexorable expansion of democratic ideals and institutions.

Some nineteenth-century democrats insisted that political reform was not enough; authentic self-government, they believed, required social revolution. Far and away the most influential version of this belief was formulated in the 1840s by Karl Marx and Friedrich Engels, who argued that a proletarian revolution was required to establish a truly free and equal society. To Marx, Engels, and their more orthodox disciples, democratic politics was always a means to an end: parties, unions, elections had no value beyond helping the proletariat obtain the power they needed to transform society. In this transformed society, organized political activity would become superfluous because class conflict would disappear. But as so often happens, the socialist parties' democratic means began to shape the ends for which they fought. Eventually the political organizations they built took on their own value, winning elections became an end in itself, democratic politics, a way of life. By the early twentieth century, the European labor movement, most prominently the Social Democratic Party in Germany, had become the most consistent and resolute defender of democratic reform.

In the nineteenth century, the most significant extension of democratic aspirations was not to the social order but rather to the national community. The French revolutionaries had insisted that because people did not belong to a ruler, they could not be traded back forth like pieces of property; nations, like individuals, had the sacred right to determine their own character and destiny. In the course of the century, self-determination came to mean the right of nations to have their own state, a fateful combination of democracy and sovereignty that made the national state the only legitimate way of organizing political space. In the middle decades of the century, Italians and Germans formed new nations; nationalities like the Polish and Irish struggled unsuccessfully to follow their example. In fact, nationality was an elastic and elusive quality, easy enough to invoke, but extraordinarily difficult to use as the foundation for a state. Even in the West, where strong states had had centuries to impose a kind of cultural homogeneity, ethnic minorities remained, while in the multinational empires of the East, the complexities of ethnic settlement meant that any potential nation state would have to contain substantial linguistic and religious minorities. Self-determination, the British political scientist Ivor Jennings remarked, 'seemed reasonable enough: let the people decide. It was in fact ridiculous because the people cannot decide until someone decides who are the people' (Anderson, 1996: p. 40).

As difficult as the question of self-determination might be within Europe itself, its problems became even greater when applied to the rest of the world, much of which remained either directly or indirectly under European control. But if the Germans and Italians had a right to their own nation, if the Irish and the Polish could aspire to nationhood, what about the populations of India, Africa, and Asia? In the nineteenth century, even progressive Europeans would have responded that these peoples were not yet ready for independence because they were barbarous. John Stuart Mill, for instance, believed that 'independence and nationality, so essential to the due growth and development of a people further advanced in improvement, are generally impediments' to uncivilized peoples (Mill, 1859: p. 252). But by the early twentieth century, advocates of national independence had challenged European influence in the ancient empires of the Manchus and Ottomans, while the ideals of democratic self-determination slowly began to attract followers throughout the colonized world. The global movement against colonization, which would be central to the history of the twentieth century, had many sources and took various forms, but its origins and eventual triumph cannot be understood without the democratic tools that had been forged within Europe itself.

The Twentieth Century

The historical period that stretched from the Congress of Vienna in 1815 to the outbreak of World War I in 1914 began with democracy's defeat and ended with its apparently irresistible, if still notably incomplete spread throughout Europe. The period from 1914 to 1945 was characterized by a series of near fatal assaults on the integrity and viability of democratic institutions. There were moments during this dark epoch when thoughtful people could readily imagine that the ideals that had inspired Rousseau and the eighteenth-century revolutionaries, having been abandoned by their advocates and defeated by their enemies, would be consigned to history's dustbin. Who in 1940 could have predicted that, at the century's end, it

would be democracy's enemies who would everywhere be in disarray?

That the years after 1914 would be so full of peril for democracy was not immediately apparent. In fact, the First World War destroyed many of democracy's most obdurate opponents, especially the Russian empire, which collapsed into revolution in 1917. Moreover, in most of Europe and America the war accelerated the extension of voting rights to women, an issue that had become increasingly contentious after the turn of the century. Finally, the war ended with the victory of the Western powers, allied since 1917 with the USA, whose president, Woodrow Wilson, proclaimed that the purpose of the war was to make 'a world safe for democracy.' Wilson's League of Nations, a keystone of the treaties signed in the spring of 1919, was designed to create a society of democratic states, in which self-government at home would nurture goodwill abroad and thus purge the world of the twin evils of tyranny and aggression.

The Wilsonian peace was supposed to be the fulfillment of the belief, held in the eighteenth century by men like Immanuel Kant and in the nineteenth by the followers of Jeremy Bentham, that democracy and peace inevitably went together. 'There are properly no other criminals than the heads of nations,' Bentham had declared, 'the subjects are always honest' (Hinsley, 1963: p. 86). Always a triumph of hope over experience, this belief was especially illusory in the years after 1919, when, having been brutalized by the war and frustrated by its outcome, the peoples of Europe were not necessarily peace-loving, while their elected leaders – including those in the USA – were not prepared to cooperate in a common defense of democratic institutions.

In retrospect, therefore, it is clear that two other events in the spring of 1919 were more significant for democracy's immediate future than Wilson's treaties. In March, Benito Mussolini formed his first fascist organization, an inchoate band of the alienated and discontented, which, within 3 years, was able to take advantage of Italy's postwar crisis and become the basis for a new government. In one state after another, parliamentary democracy collapsed in the twenties and thirties, and nowhere more consequently than in Germany, where Mussolini's admirer, Adolf Hitler, created a dynamic regime based on race, radical nationalism, and anti-communism. Mussolini's fascism and Hitler's National Socialism were at once the enemies and the perversions of democratic politics. Both of them blended dictatorial practice with the trappings of participatory politics – a mass party, rallies and demonstrations, and plebiscites.

A few weeks after Mussolini formed his fascist organization in Milan, Lenin established the Third International in Moscow. Lenin's hopes for world revolution, still very much alive in 1919, were soon disappointed. Contrary to Marxist theory and his own expectations, Lenin was faced with the need to build a socialist society in Russia. This required the violent repression of dissent by the revolutionary regime and then, under Lenin's successor, Joseph Stalin, the ruthless use of state power to create a new social order from above. Tens of millions died in the doomed attempt to turn the USSR into a workers' paradise. Like fascism, which claimed to rule on behalf of the nation, Soviet Communism was a perversion of nineteenth century democratic aspirations which sought to conceal a brutal tyranny behind a facade of cynical democratic rhetoric and empty participatory practice. That so many intelligent people outside of the USSR were drawn to communism in the 1920s and 1930s was a symptom of the political malaise that afflicted democratic regimes everywhere in Europe and America.

The second global war of the twentieth century ended in 1945 with the defeat of the fascist powers. The interwar political spectrum, in which democratic regimes had faced enemies from both the left and the right, was now dramatically simplified; radical rightwing parties were discredited, outlawed, and, in some places, vigorously repressed. Almost all of the regimes that emerged from the war's wreckage declared themselves to be democratic. In the East, 'people's democracies' were formed under the auspices of the USSR and, with the exception of Yugoslavia and Albania, with the assistance of Soviet armies of occupation; in the West, parliamentary regimes were allied with and, to varying degrees, influenced by the USA. This bipolar division of the continent lasted until 1989, when the creation of a reformist regime in the USSR opened the way for democratic movements throughout Eastern Europe. With remarkable speed and, except in Romania, without violence, the communist regimes were driven from power and new, authentically democratic governments were elected to take their place. With the collapse, first of the Soviet Imperium and then of the USSR itself, a new era in the history of democracy – with a new set of problems and possibilities – clearly began.

Among the casualties of World War II was European colonialism. The principle of national self-determination, proclaimed by Wilson at the end of World War I and reaffirmed by Franklin Roosevelt and Winston Churchill at the beginning of the second, was not applied to the non-European world without great delay and difficulty. Obviously Japan lost its overseas possessions when it lost the war. While neither Britain nor France, who were on the winning side in 1918 and 1945, wanted to abandon their colonies, they lacked both the ability and the will to maintain them in the face of indigenous resistance, the hostility of both the USA and the USSR, and the reluctance of their own peoples to support a vigorous defense of their empires. Sometimes peacefully, sometimes after violent wars of liberation, Europe's former colonies achieved independence; by the 1980s virtually no residue of direct imperial rule remained. Although the struggle against colonialism was carried out in the name of national self-determination, it proved to be extremely difficult to plant democratic institutions in the new states. With a few notable exceptions, most significantly India, the world's largest democracy, most of Europe's former colonies, especially in Africa, fell under authoritarian regimes, often based on the power of the military. For many of the world's population, therefore, the promise of democracy remained unfulfilled.

Conclusion

Despite democracy's disappointing record in much of Africa and Asia, there are more functioning democracies in the world at the beginning of the twenty-first century than at any other time in history. Furthermore, alternative sources of political authority have apparently disappeared; even dictatorial regimes usually feel obliged to exercise power in the people's name. Elections, even when they are manifestly fraudulent,

have become the essential rituals through which authority is legitimized.

Although the alternatives to democracy have largely disappeared, at least in theory, debates about democracy's meaning continue. Some of these debates are new versions of old contests about the composition of the demos, the procedures best suited to guarantee democratic representations, the social and cultural preconditions of popular rule, and the proper scope of democratic politics. Some of the contemporary debates over democracy's meaning reflect new sources of conflict, such as the question of how – or whether – ethnic minorities should be shielded from the impact of majority rule? Others concern the extension of democratic principles into families, schools, religious institutions, health care systems.

These debates, as painful and occasionally destructive as they sometimes are, reflect the continued vitality of the democratic tradition. A more serious danger to democracy is a growing skepticism about whether democratic institutions can solve the most significant problems people face in their everyday existence. To the rich, democracy sometimes seems superfluous, an unnecessary distraction from the challenges and opportunities of private life. In the USA, for instance, less than half of those eligible turn out to vote in national elections. To the poor, democracy can seem irrelevant, a woefully inadequate antidote to the poisonous power of poverty, violence, and political corruption. Over the past two centuries, the democratic vision has survived defeat and outlived its historic enemies; if it is to survive and flourish in the new century, it must recapture – and in some places, attain for the first time – its hold on ordinary men and women's political imagination. In the twenty-first century the additional issue is whether democracy can adapt to theocratic conceptions of the state and civil society, which are seen to be a significant challenge to democratic ideals in many parts of the world. In the aftermath of failed democratic revolutions in the Arab world and elsewhere, the question of democracy as a global form of government in once again being questioned.

Abstract

Normative democratic theory deals with the ethical foundations of democracy and democratic institutions. It does not offer in the first instance a scientific study of those societies that are called democratic. It aims to provide an account of when and why democracy is ethically desirable as well as ethical principles for guiding the design of democratic institutions. It is inherently interdisciplinary and must call on the results of political science, sociology, and economics in order to give this kind of concrete guidance. This brief outline of normative democratic theory focuses attention on three distinct issues in recent work. First, it outlines some different approaches to the question of why democracy is morally desirable at all. Second, it explores the problem of the rationality of participation in large democratic societies given the inevitably small impact of participants on the outcomes. It also discusses blueprints of democratic institutions for dealing with this. Third, it surveys different accounts of the proper characterization of equality in the processes of representation. The last two parts display the interdisciplinary nature of normative democratic theory.

Foundational Questions

To fix ideas, the term 'democracy' refers very generally to a method of group decision making characterized by a kind of equality of input among the participants. That equality may be the mere formal equality of one person, one vote in an election for representatives to an assembly, or it may be more robust, including equality in the processes of deliberation and coalition building. 'Democracy' may refer to any of these political arrangements. Normative democratic theorists attempt to determine which one of these kinds of arrangements is desirable, ethically speaking, and in what contexts. For instance, Joseph Schumpeter (1956) argues, with some force, that the first highly formal kind of democracy is highly desirable while the second is dangerous. On the other hand, Jean-Jacques Rousseau (1967) is apt to argue that the first kind of democracy is akin to slavery while only robustly egalitarian democracies have political legitimacy. To evaluate their arguments we must decide on the merits of the different principles and conceptions of humanity and society from which they proceed.

The Justification of Democracy

We can evaluate democracy ethically along at least two different dimensions. We can evaluate a group decision-making method in terms of the outcomes of using it and compare the values of those outcomes with those of other possible methods of political decision making. We can also evaluate democracy in terms of qualities that are inherent in the method itself. We can ask whether there is something inherently fair about making democratic decisions on matters on which people disagree.

Instrumental Values

The instrumental values often attributed to democracy can be broadly classed into two categories: the quality of the resulting legislation and the impact of democracy on the characters of the participants. John Stuart Mill (1991) argued that democratic ways of deciding tend to be superior to nondemocratic ways on account of the fact that they produce superior legislation in three distinct ways. Strategically, democracy is thought to produce superior outcomes to other forms of rule just because it forces decision makers to take into account the interests, rights and opinions of most people in society. Since democracy gives some political power to each, more people are taken into account than under aristocracy or monarchy.

Epistemologically, democracy is thought to be the best decision-making method on the grounds that it is generally more reliable in helping participants discover the right decisions. Since democracy brings a lot of people into the process of decision making, it can take advantage of many sources of information and critical assessment of laws and policies. Democratic decision making tends to be more informed than other forms about the interests of citizens and the causal mechanisms necessary to advance those interests. Furthermore, the broad-based discussion typical of democracy enhances the critical assessment of the different moral ideas that guide decision makers.

Regarding its effects on character, many have noted with Mill and Rousseau that democracy tends to make people stand up for themselves more because it makes collective decisions depend on them more than monarchy or aristocracy do. Hence, in democratic societies individuals are encouraged to be more autonomous. In addition, democracy tends to get people to think carefully and rationally more than other forms of rule because it makes a difference whether they do or not. Finally, some have argued that democracy tends to enhance the moral qualities of citizens. When they participate in making decisions, they have to listen to others, they are called upon to justify themselves to others and they are forced to think in part in terms of the interests of others. Some have argued that when people find themselves in this kind of circumstance, they come genuinely to think in terms of the common good and justice. Hence some have argued that democratic processes tend to enhance the autonomy, rationality, and morality of participants. Since these beneficial effects are thought to be

worthwhile in themselves, they count in favor of democracy and against other forms of rule.

Some argue in addition that the above effects on character also tend to enhance the quality of legislation. A society of rational, autonomous, and moral decision makers is more likely to produce good legislation than a society ruled by a self-centered person or small group of persons who rule over slavish and unreflective subjects.

More detailed knowledge of the effects of political institutions can be used to discriminate in favor of particular kinds of democratic institutions or modifications of them. For instance, in the United States, James Madison (1788) argued in favor of a fairly strong federal government on the grounds that local governments are more likely to be oppressive to minorities. Of course, the soundness of any of the above arguments depends on the truth or validity of the associated substantive views about justice and the common good as well as a causal theory of the consequences of different institutions.

It is also the case that many theorists argue against any kind of democracy on instrumental grounds. Hobbes (1968) argues that democratic institutions are inferior to monarchical government on the grounds that they are more likely to breed destabilizing dissension among subjects. Plato (1974) argues that democracy is inferior to various forms of monarchy, aristocracy, and even oligarchy on the grounds that democracy tends to undermine the expertise necessary to properly governed societies. Some recent thinkers have argued in favor of giving over complete control over society to the market, on the grounds that democracy tends to produce serious economic inefficiencies. More modest versions of these arguments have been used to justify modification of democratic institutions.

Instrumentalism

Instrumentalists argue that these instrumental values of the democratic process are the only bases on which to evaluate democracy or compare it with other forms of political decision making. The standards one uses depend on one's conception of a just and good society. For example, libertarian instrumentalists such as Friedrich Hayek (1960) argue that democracy is desirable only to the extent that it protects liberty and private property.

Noninstrumental Values

Few theorists deny that political institutions must be at least in part evaluated in terms of the outcomes of having those institutions. Some argue, in addition, that some forms of decision making are morally desirable independent of the consequences of having them. A variety of different approaches have been used to show that democracy has this kind of intrinsic value. The most common of these come broadly under the rubrics of liberty and equality.

Liberty

Some argue that the basic principles of democracy are founded in the idea that each individual has a right to liberty. Democracy, it is said, extends the idea that each ought to be master of his or her life to the domain of collective decision making. First, each person's life is deeply affected by the larger social, legal, and cultural environment in which he or she lives. Second, only when each person has an equal voice and vote in the process of collective decision making will each have control over this larger environment. Thinkers such as Carol Gould (1988) conclude that only when some kind of democracy is implemented will individuals have a chance at self-government. Since individuals have a right to self-government, they have a right to democratic participation. This right is established at least partly independently of the worth of the outcomes of democratic decision making. The idea is that the right to self-government gives one a right, within limits, to do wrong. Just as an individual has a right to make some bad decisions for himself or herself, so a group of individuals have a right to make bad or unjust decisions for themselves. Here we can see the makings of an argument against instrumentalism. To the extent that an instrumentalist wishes to diminish a person's power to contribute to the democratic process for the sake of enhancing the quality of decisions, he or she is committed to thinking that there is no moral loss in the fact that our power has been diminished; but if the liberty argument is correct our right to control our lives is violated by this.

One major difficulty with this line of argument is that it appears to require that the basic rule of decision making be consensus or unanimity. If each person must freely choose the outcomes that bind him or her, then those who oppose the decision are not self-governing. They live in an environment imposed on them by others. So only when all agree to a decision are they freely adopting the decision.

The trouble is that there is rarely agreement on major issues in politics. Indeed, it appears that one of the main reasons for having political decision-making procedures is that they can settle matters despite disagreement. Hence it is hard to see how any political decision-making method can respect everyone's liberty.

Democracy as Public Justification

One distant relative of the self-government approach is the account of democracy as a process of public justification defended by, among others, Joshua Cohen (1998). The idea behind this approach is that laws and policies are legitimate to the extent that they are publicly justified to the citizens of the community. Public justification is justification to each citizen as a result of free and reasoned debate among equals. Citizens justify laws and policies to each other on the basis of mutually acceptable reasons. Democracy, properly understood, is the context in which individuals freely engage in a process of reasoned discussion and deliberation on an equal footing. The ideas of freedom and equality provide guidelines for structuring democratic institutions.

The aim of democracy as public justification is reasoned consensus among citizens. However, a serious problem arises when we ask about what happens when disagreement remains. Two possible replies have been suggested to this kind of worry. It has been urged that forms of consensus weaker than full

consensus are sufficient for public justification and that the weaker varieties are achievable in many societies. For instance, there may be consensus on the list of reasons that are acceptable publicly but disagreement on the weight of the different reasons. Or there may be agreement on general reasons but disagreement about particular interpretations of those reasons. What would have to be shown here is that such weak consensus is achievable in many societies and that the disagreements that remain are not incompatible with the ideal of public justification.

Equality

Many democratic theorists have argued that democracy is a way of treating persons as equals when there is good reason to impose some kind of organization on their shared lives, but they disagree about how best to do it. On one version, defended by Peter Singer (1973), when people insist on different ways of arranging matters properly, each person in a sense claims a right to be dictator over their shared lives. However, these claims to dictatorship cannot all hold up. Democracy embodies a kind of peaceful and fair compromise among these conflicting claims to rule. Each compromises equally on what he or she claims as long as the others do, resulting in each having an equal say over decision making. In effect, democratic decision making respects each person's point of view on matters of common concern by giving each an equal say about what to do in cases of disagreement.

One difficulty is that this view relies on agreement much as the liberty views described above. What if people disagree on the democratic method or on the particular form democracy is to take? Are we to decide these latter questions by means of a higher order procedure? And if there is disagreement on the higher order procedure, must we also democratically decide that question? The view seems to lead to an infinite regress. Another egalitarian defense democracy asserts that it embodies the equal consideration of the interests of the citizens of a society when there is disagreement about how best to organize their shared life. On this account, equal consideration of interests requires that individuals' judgments be taken into account equal when there is disagreement. Respect for each citizen's judgment is grounded in the fallibility of everyone's judgment as well as the generally recognized tendency of the moral judgments of persons to be biased toward their own interests. Each citizen would have good reason to think that his or her interests were not being given the same weight as others if he or she had less decision-making power than the others. On this account, since each person has a preeminent interest in being recognized as an equal member of the community, only equality in decision-making power is compatible with equal consideration of interests. The principle of equal consideration of interests also implies limits to what can be up for democratic control and so the infinite regress noted above is avoided.

Democratic Citizenship

A vexing problem of democratic theory has been to determine whether ordinary citizens are up to the task of governing a large society. There are three distinct problems here. First, Plato argued that some people are innately more intelligent than others and that those persons ought to rule. Second, others have argued that a society must have a division of labor. If everyone were engaged in the complex and difficult task of politics, little time or energy would be left for the other essential tasks of a society. Conversely, if we expect most people to engage in other difficult and complex tasks, how can we expect them to have the time and resources sufficient to devote themselves intelligently to politics?

Third, since individuals have so little impact on the outcomes of political decision making in large societies, they have little sense of responsibility for the outcomes. Some have argued that it is not rational to vote since the chances that a vote will affect the outcome of an election are nearly indistinguishable from zero. Worse still, Anthony Downs (1957) has argued that almost all of those who do vote have little reason to become informed about how best to vote. On the assumption that citizens reason and behave roughly according to the Downsian model, either the society must in fact be run by a relatively small group of people with minimal input from the rest or it will be very poorly run.

These observations pose challenges for any robustly egalitarian or deliberative conception of democracy. Without the ability to participate intelligently in politics one cannot use one's votes to advance one's aims, nor can one be said to participate in a process of reasoned deliberation among equals. So, either equality of political power implies a kind of self-defeating equal participation of citizens in politics or a reasonable division of labor seems to undermine equality of power.

Plato and Hobbes argued against democracy in any form on these grounds. Some modern theorists of democracy, called elite theorists, have argued against any robustly egalitarian forms of democracy on these grounds. They argue that high levels of citizen participation tend to produce bad legislation designed by demagogues to appeal to poorly informed and overly emotional citizens. They look upon the alleged apathy and uninformedness of citizens evidenced in many empirical studies in the 1950s and 1960s as highly desirable social phenomena. Joseph Schumpeter's assertion that the "democratic method is that institutional arrangement for arriving at political decisions in which individuals acquire the power to decide by means of a competitive struggle for the people's vote" (Schumpeter, 1956: p. 269) still stands as a concise statement of the elitist view. In this view, the emphasis is placed on responsible political leadership. Political leaders are to avoid divisive and emotionally charged issues and make policy and law with little regard for the fickle and diffuse demands made by ordinary citizens.

An approach that is in part motivated by the concerns above but that attempts to avoid elitism is the interest group pluralist account of politics. Robert Dahl's early statement of the view is very powerful. "In a rough sense, the essence of all competitive politics is bribery of the electorate by politicians… The farmer… supports a candidate committed to high price supports, the businessman… supports an advocate of low corporation taxes… the consumer… votes for candidates opposed to a sale tax" (Dahl, 1959: p. 69). In this conception of the democratic process, each citizen is a member of an interest group with

narrowly defined interests that are closely connected to their everyday lives. On these subjects citizens are supposed to be fairly well informed and interested in having an influence. On this account, democracy is not rule by the majority but rather rule by coalitions of minorities.

The account ensures that individuals can participate roughly as equals to the extent that it narrowly confines the issues with which each individual is concerned.

A third approach inspired by the kinds of problems above may be called the neoliberal approach to politics favored by public choice theorists such as James Buchanan and Gordon Tullock (1965). Against elite theories, they contend that elites and their allies will tend to expand the powers of government and bureaucracy for their own interests and that this expansion will occur at the expense of a largely inattentive public. They argue against the interest group pluralist theorists that the problem of participation occurs within interest groups more or less as powerfully as among the citizenry at large. Only some interest groups are likely to succeed in organizing to influence the government. Hence only some interest groups will succeed in influencing government and they will do so largely for their own benefit while spreading the costs to others.

Neoliberals argue that any way of organizing a large and powerful democratic state is likely to produce serious inefficiencies. They infer that one ought to transfer many of the current functions of the state to the economic market and limit the state to the enforcement of basic property rights and liberties. These can be more easily understood and brought under the control of ordinary citizens.

But the neoliberal account of democracy must answer to two large worries. First, citizens in modern societies have more ambitious conceptions of social justice and the common good than are realizable by the minimal state. The neoliberal account thus implies a very serious curtailment of democracy of its own. More evidence is needed to support the contention that these aspirations cannot be achieved by the modern state. Second, the neoliberal approach ignores the problem of large private concentrations of wealth and power that are capable of pushing small states around for their own benefit and imposing their wills on populations without their consent. The assumptions that lead neoliberals to be skeptical about the large modern state imply equally disturbing problems for a neoliberal society.

A considerable amount of the literature in political science and the economic theory of the state are grounded in the assumption that individuals act primarily and perhaps even exclusively in their self-interest narrowly construed. The problem of participation and the accounts of the democratic process described above are in large part dependent on this assumption. While these ideas have generated interesting results and have become ever more sophisticated, there has been a growing chorus of opponents. Against the self-interest axiom, defenders of deliberative democracy and others claim that citizens are capable of being motivated by a concern for the common good and justice. They also claim, with Mill and Rousseau, that such concerns are not merely given prior to politics but that they can evolve and improve through the process of discussion and debate in politics. They assert that much debate and discussion in politics would not be intelligible were it not for the fact that citizens are willing to engage in open-minded discussion with those who have distinct morally informed points of view. Empirical evidence suggests that individuals are motivated by moral considerations in politics in addition to their interests. Accordingly, many propose that democratic institutions be designed to support the inclination to engage in moral and open-minded discussion with others.

Once we approach the idea of citizenship from a moral point of view and we recognize the importance of a division of labor, the question arises of what the appropriate role for a citizen in a democracy is. If we think that citizens are too often uninformed, we should ask two questions. What ought citizens have knowledge about in order to fulfill their role? What standards ought citizens' beliefs live up to in order to be adequately supported? Some have proposed that citizens know about their particular sectors of society and not others. We have seen that this view has a number of difficulties. Christiano (1996) proposes, along with others, that citizens must think about what ends the society ought to aim at and leave the question of how to achieve those aims to experts. This kind of view needs to answer to the problem of how to ensure that politicians, administrators, and experts actually do attempt to realize the aims set by citizens. And it must show how institutions can be designed so as to establish the division of labor while preserving equality among citizens. But if citizens genuinely do choose the aims and others faithfully pursue the means to achieving those aims, then citizens are in the driver's seat in society.

It is hard to see how citizens can satisfy any even moderate standards for beliefs about how best to achieve their political aims. Knowledge of means requires an immense amount of social science and knowledge of particular facts. For citizens to have this kind of knowledge generally would require that we abandon the division of labor in society. On the other hand, citizens do have first-hand and daily experience with thinking about the values and aims they pursue. This gives them a chance to satisfy standards of belief regarding what the best aims are. Still the view is not defensible without a compelling institutional answer to the question of how to ensure that others are genuinely pursuing the means to achieve the aims specified by citizens.

Legislative Institutions

A number of debates have centered on the question of what kinds of legislative institution are best for a democratic society. What choice we make here will depend heavily on the kind of underlying ethical justification of democracy, our conception of citizenship, and our empirical understanding of political institutions and how they function. The most basic types of formal political representation available are single-member district representation, proportional representation, and group representation. In addition, many societies have opted for multicameral legislative institutions. In some cases, combinations of the above forms have been tried.

Single-member district representation returns single representatives of geographically defined areas containing roughly equal populations to the legislature and is present most prominently in the USA and the UK. The most common form of proportional representation is party-list proportional representation. In a simple form of such a scheme, a number of

parties compete for election to a legislature that is not divided into geographical districts. Parties acquire seats in the legislature as a proportion of the total number of votes they receive in the population as a whole. Group representation occurs when the society is divided into nongeographically defined groups such as ethnic or linguistic groups or even functional groups such as workers, farmers, and capitalists and returns representatives to a legislature from each of them.

Many have argued in favor of single-member district legislation on the grounds that it has appeared to them to lead to more stable government than other forms of representation. The thought is that proportional representation tends to fragment the citizenry into opposing homogeneous camps that adhere rigidly to their party lines and that are continually vying for control over the government. Since there are many parties and they are unwilling to compromise with each other, governments formed from coalitions of parties tend to fall apart rather quickly. The post-War experience of governments in Italy appears to confirm this hypothesis. Single-member district representation, in contrast, is said to enhance the stability of governments by virtue of its favoring a two-party system of government. Each election cycle then determines which party is to stay in power for some length of time.

Charles Beitz (1989) argues that single-member district representation encourages moderation in party programs offered for citizens to consider. This results from the tendency of this kind of representation toward two-party systems. In a two-party system with majority rule, it is argued, each party must appeal to the median voter in the political spectrum. Hence they must moderate their programs to appeal to the median voter. Furthermore, they encourage compromise among groups since they must try to appeal to a lot of other groups in order to become part of one of the two leading parties. These tendencies encourage moderation and compromise in citizens to the extent that political parties, and interest groups, hold these qualities up as necessary to functioning well in a democracy.

In criticism, advocates of proportional and group representation have argued that single-member district representation tends to muffle the voices and ignore the interests of minority groups in the society. Minority interests and views tend to be articulated in background negotiations and in ways that muffle their distinctiveness. Furthermore, representatives of minority interests and views often have a difficult time becoming elected at all in single-member district systems, so it has been charged that minority views and interests are often systematically underrepresented. Sometimes these problems are dealt with by redrawing the boundaries of districts in a way that ensures greater minority representation. The efforts are invariably controversial since there is considerable disagreement about the criteria for apportionment. In proportional representation, by contrast, representatives of different groups are seated in the legislature in proportion to citizens' choices. Minorities need not make their demands conform to the basic dichotomy of views and interests that characterize single-member district systems so their views are more articulated and distinctive as well as better represented.

Another criticism of single-member district representation is that it encourages parties to pursue dubious electoral campaign strategies. The need to appeal to a large, diverse, and somewhat amorphous sector of the population can very often be best met by using ambiguous, vague, and often irrelevant appeals to the citizens. Thus, instead of encouraging reasonable compromise, the scheme tends to support tendencies toward ignorance, superficiality, and fatuousness in political campaigns and in the citizenry. It encourages political leaders to take care of the real issues of politics in back rooms while they appeal to citizens by means of smoke and mirrors. Of course, those who agree in the main with the elitist-type theories will see nothing wrong in this; indeed, they may well champion this effect. Proportional representation requires that parties be relatively clear and up front about their proposals, so those who believe that democracy is ethically grounded in the appeal to equality tend to favor proportional representation.

Advocates of group representation such as Iris Marion Young (1993) have argued that some historically disenfranchised groups may still not do very well under proportional representation. They may not be able to organize and articulate their views as easily as other groups. Also, minority groups can still be systematically defeated in the legislature and their interests may be consistently set back even if they do have some representation. For these groups, some have argued that the only way to protect their interests is legally to ensure that they have adequate and even disproportionate representation.

One worry about group representation is that it tends to freeze some aspects of the agenda that might be better left to the choice of citizens. For instance, consider a population that is divided into linguistic groups for a long time, and suppose that only some citizens continue to think of linguistic conflict as important. In the circumstances, such schemes may tend to be biased in an arbitrary way that favors the views or interests of those who do think of linguistic conflict as important.

Abstract

The responses to core questions of democracy by classic theorists, including Aristotle, John Locke, Jean-Jacques Rousseau, Alexis de Tocqueville, John Stuart Mill, and Joseph Schumpeter, are surveyed by way of introduction to contemporary theories that draw on them. These include participatory democracy, catallaxy and collective choice theories, deliberative democracy, power-political pluralism, and radical-democratic pluralism. Also discussed is a selection of persisting problems addressed by democratic theorists.

The two generic questions to which answers are either given or presupposed by all democratic theorists are: What is democracy? and Why (if at all) ought democracy to be valued? The responses of Aristotle (384–322 BC), in this as in many other domains of Western theorizing, usefully set the stage for summaries of the main alternatives.

Aristotle

With typical attention to nuance, Aristotle (1986[*c*.320 BC]) distinguishes between ideal conceptions of how a political society might be governed and ways that they are governed in actual practice. In either case, rule might be in the hands of one person, of a few people, or of many people. In the ideal world, the latter situation is called by him a 'polity' to be distinguished from a 'royalty' or rule by one and rule by a few, called 'aristocracy.' What makes all of these conceptions ideal is that the one, the few, or the many rule with a view to promoting the common good of the entire society. Such rule is almost never attained in actuality, where it is exercised instead in accord with the specific interests of the rulers. Rule by and for one person is 'tyranny' and by a few people, 'oligarchy.' Aristotle reserves the term 'democracy' to refer to the remaining category, where the many rule in their own interests.

As to his evaluations, Aristotle holds that the best rule in an ideal world would be royalty, followed by aristocracy, and then polity. In the real world, however, Aristotle anticipated by over two millennia the often-cited opinion of Winston Churchill that democracy is the worst form of government except for all the others. Aristotle's main ground for viewing democracy as the most tolerable realistic choice is that at least the largest number of people profit from its self-serving rule. Also, there is something to be gained from pooling many people's experiences in formulating policies, and the dangers of majority discontent confronted by undemocratic societies are averted.

Throughout the history of democratic theory, the boundary between it and political-scientific considerations is often blurred. Indeed, a case can be made that each of political science and political theory gains from their interaction. Aristotle's distinction between real and ideal rule is a case in point. His view that ideal rule is rarely enacted is based not on speculation but on study of actual political societies in the ancient world, where Aristotle saw very few approximations in practice: royalty during the reign of certain generals in Sparta, polity for a time after the rule of Solon in Athens. Another example is Aristotle's equation of rule of the many with rule of the poor. While admitting of theoretical explanation for him, this assimilation is largely an empirical claim. Also empirical are his views about the preconditions for a stable and virtuous citizenry. These include a large middle class, a universal – for boys – public educational system, and an appropriate size.

Locke and Rousseau

Historicistic accounts of democratic theories see them as expressing, rationalizing, or otherwise being embedded in the social and economic circumstances of their times. An example is C.B. Macpherson's interpretation of British political theorizing in the seventeenth century as reflection of and support for the nascent capitalism of that time (2011[1962]). This article abstracts from such historical accounts while recognizing that there is much to be learned from them. Still, it should be noted that democratic theorists themselves differ in how much attention they pay to actual practices called democratic.

Virtually all approaches to democratic theory address all three of the meaning of democracy, the value of democracy, and actual democratic practices, but they differ depending on which of these is the lead consideration. Aristotle generalizes a view about the meaning of democracy from his surveys of democratic practices, which also motivate his evaluations of its various forms. An alternative strategy is to begin with the value of democracy. This approach is illustrated in the political theory of John Locke (1632–1704). Like other political philosophers in the 'social contract' tradition, Locke is primarily concerned to identify the conditions that make political institutions and practices legitimate.

Political society for the social contract theorists, in modern times stretching from Thomas Hobbes through John Rawls, should be thought of as the result (or as if it were the result) of people in a prepolitical state of nature agreeing to transfer some or all of their individual powers to a political authority. To the extent that the authority comports itself in accord with the original intentions of the contractors, it is legitimate. Thus for Hobbes (1588–1679), the intent was to preserve the peace, and

failure to do so challenges the legitimacy of a sovereign power (1968[1651]).

The intent of contractors in a state of nature for Locke is to preserve their individual freedoms along with their lives and property. Unlike Hobbes, for whom democratic or autocratic forms of political authority were a matter of choice for his entirely self-interested contractors (his recommendation being for monarchal autocracy), Locke maintained that only a certain form of democracy could be legitimate, namely majority rule issuing in representative government. The majority embodies the will of the entire community, and the representatives it selects to govern are charged with acting in accord with this will, which includes preservation of individual liberty, life, and property. Thus for Locke, the value of democracy is its protection of these things, and democracy itself is majority rule and representative government (1962[1690]).

The approach of Jean-Jacques Rousseau (1712–78) illustrates how following a similar methodology by different theorists can lead to alternative or even opposed viewpoints on democracy. Like Locke, Rousseau appeals to a social contract. He shares Hobbes' conception of original contractors as self-interested, but he maintains that the very act of coming together to seek consensus on a desirable form of political society changes people's nature to ones valuing collective goods (1968[1762]). The resulting prescriptions regarding political society differ from Locke's in two major respects.

For Locke, some matters must be outside of governmental control, in particular those things that impact individual freedom, life, or property. By contrast, for Rousseau, all aspects of human interaction are subject to the power of the body politic. What is supposed to keep this from being oppressive is that its members, in virtue of the character transformation they have undergone, will act to promote the common good, and, in a second departure from Locke, their power is not exercised by representatives but directly by the populace itself.

Like Aristotle, Rousseau recognized that this is an ideal seldom fully realized. Thus, he employed the term 'democracy' to refer to a situation only approximating ideal self-rule. This is representative democracy where representatives are strictly delegated by a majority that, for its part, is motivated by concern for common interests (famously called by him 'the general will'). Such rule is possible in relatively small communities where legislative officials are selected by lot. Rousseau's views are almost always referred to by subsequent defenders of what came from around 1960 to be called 'participatory democracy.'

In its strongest form, participatory democracy merges with anarchism, where a self-governing population dispenses with government altogether. In a weaker form, participatory democrats can accommodate representative government, provided representatives are strictly delegated by the citizens who select them and as many of the functions of a state as possible are carried out directly by citizens (Pateman, 1970; Mansbridge, 1983; Barber, 1984). One value claimed for participatory democracy is that it draws on the expertise of ground-level citizen experiences in formulating and executing policies. Participatory democrats also echo a 'civic republican' theme in Rousseau's view about the character-building dimension of the social contract. This is the hypothesis that collective experience in self-government promotes socially virtuous citizenship. For modern-day civic republicans, this is important for promoting values that both respect individual autonomy and encourage the pursuit of common goods (Maynor, 2003).

de Tocqueville and Mill

In an extended study tour of America in the early 1830s, the French aristocrat Alexis de Tocqueville (1805–59) came to appreciate the vibrancy of that early democracy, which he attributed in large part to the experiences of its citizens in local, town governance unconstrained by European traditional conservatism and inequalities. His conception of democracy is an example of one focused on the literal meaning of the word, namely 'rule by the people' or 'popular sovereignty.' "The people," he concluded, "reign over the American political world as God reigns over the universe" (1969[1835–40]: p. 60).

The advantages de Tocqueville saw in this democracy are not unlike those extolled by participatory democrats – an engaged and energized population making valuable contributions to governance. However, not sharing the Rousseauean image of a homogenous public, he identified as a major problem for the American or any other democracy that a minority might be oppressed by a majority, and he coined the phrase 'the tyranny of the majority' to describe this possibility. Majoritarian democracy not only makes such oppression possible but also disguises it because the majority, as Locke claimed, is supposed to embody the legitimate will of the entire society. This, in turn, is facilitated by the fact that while rulers in a monarchy are identifiable individuals, in a democracy, ultimate rule is supposed to be exercised by the abstract entity of 'the people.'

Mill

John Stuart Mill (1806–73) furthered Locke's defense of representative democracy, though he thought that it should be supplemented when feasible by opportunities for direct citizen participation. Mill also endorsed de Tocqueville's warnings about majority tyranny. Not only can a majority oppress a minority but it can also suppress freedom of speech and the like in ways that rebound negatively on democracy itself. Mill's solution was to prescribe combining representative democracy with legally binding protections of individual liberties, thus providing what is generally taken to be the classic expression of the theory of liberal democracy (1991[1861]).

As to the value of democracy, one finds two considerations. As a utilitarian in ethics (2002[1863]), Mill saw democracy as aggregating preferences in such a way as to yield the greatest amount of citizen satisfaction. Additionally, in connection with his endorsement of direct participation, Mill valued democracy for developing people's personally enriching and socially beneficial potentials. His nuanced deployment of utilitarian theory makes these two goals of democracy compatible in his eyes, but subsequent theorists typically divide on whether democracy can or should achieve more than the aggregation of preferences.

Schumpeter

Joseph Schumpeter (1883–1950) is often credited with inaugurating the self-described 'realist' school of democratic theory. He took the strategy of generalizing a theory of democracy from the example of existing practices called democratic to its limit. If one looks at such practices, he held, one sees that they mainly involve politicians and political parties competing with one another for the popular vote. This, Schumpeter concluded, is all that democracy is (1962[1942]: p. 269). He took the idea of popular sovereignty to be a myth because even people voting for the same candidates often do so for different reasons. Similarly, he denied that democracy could be construed as promoting the common good, since for him there is no such thing.

The principal value of democracy for Schumpeter is that leaders cannot act in entirely irresponsible ways, depending on elections to remain in power. Contrary to participationists, he thought citizen engagement in governing should be minimized so as not to hamper professional government bureaucracies.

Contemporary Variations

Main theories of democracy today present a large array of approaches to the primary questions of democratic theory (surveyed in Cunningham (2002) and Held (1996)), but in their basic orientations, they are all variations or combinations of the classic alternatives. For example, 'associative democracy,' where voluntary self-governing organizations – of workers, consumers, producers, social movements, and the like – have special access to a central government or wherever possible replace it, is informed by the values of participatory democracy (Hirst, 1994). Macpherson strives to combine liberal and participatory democracy guided by neo-Aristotelian values and a Marx-like critique of capitalism (2012: Chapter 5). Michael Sandel draws on the civic republican dimension of the thought of Rousseau and others to advocate an anti-individualistic, communitarian version of democracy (1996). It is also worth noting that while not seeing the new electronic media as offering a unique form of democracy, many now look to it to enhance democratic practices and institutions variously conceived (see the contributions to Jenkins and Thorburn, 2004).

Two current approaches stand out for drawing the largest contemporary following – catallaxy – especially as deployed by collective choice theories and deliberative democracy.

Catallaxy

Also in the mode of thinking of Schumpeter was a fellow Austrian, Friedich von Hayek (1899–1992), who popularized the idea of 'catallaxy' or the application of economic methods to the study of politics (1976: Chapter 10). The views of Schumpeter and von Hayek found their most enthusiastic proponents among certain theorists of democracy in the United States. Anthony Downs took as his main thesis that parties in democratic politics are primarily concerned to formulate "whatever policies they believe will gain the most votes, just as entrepreneurs produce whatever product they believe will gain the most profits." (1957: p. 295).

Primary analytic tools of those in this tradition are taken from rational choice theory in which it is ascertained what means, given available resources, it is rational for individuals to take in realizing their goals, where the goals are not themselves evaluated. The species of the approach variously called social or public or collective choice theory employs this method in situations where collective decisions are being made such as voting to select a government. (Useful summaries are by Harden (1982) and Ordeshook (1992).)

Early deployment of these methods challenged some core tenets of democratic theory, as in the conclusion of James Buchanan and Gordon Tullock, that sometimes majority rule is an irrational decision procedure (1962). It also posed seemingly intractable problems for democratic decision-making. At the core of some voter 'paradoxes' described by John Kenneth Arrow (1951, and Riker (1982) is the possibility of stalemate due to a cyclical majority when more than two choices confront voters.

Downs addresses the problem of voter abstention not as a matter of figuring out how to get people to the polls but as a problem of collective rationality. Because the likelihood of any one vote making a crucial difference is so low and because there are personal costs to taking the time and effort to vote, the rational citizen will not vote at all. Subsequent collective choice theorists have drawn on increasingly sophisticated rational choice tools, such as game theory, to explicate democratic decision-making and flag problems it confronts. (An example of very many is Strom, 1992.) Insofar as theory in this mode has practical application, it is to analyze and recommend legislative and voting models and methods. These include questions about the relative superiority of presidential or parliamentary systems of government, the virtues or otherwise of multiparty systems, first-past-the-post voting rules versus proportional representation, ranked preference voting, runoff elections, and so on.

Like almost all other liberal-democratic theorists, those in this tradition think of democracy exclusively in formal representative-democratic terms. Activities within religious organizations, social movements, interest groups, or other organizations of civil society are seldom, if ever, addressed. Formally structured majority voting is seen as the core of democracy and is to be valued (if it can overcome the voter paradoxes) as a way of making collective decisions. In this, the catallactic theorists differ from participatory democrats, many of whom agree with Benjamin Barber's view of voting as among "the thinnest features of democracy" and majority rule as "a tribute to the failure of democracy" (1984: p. 198).

Deliberative Democracy

Deliberative democrats also strongly resist an exclusive focus on voting and simple majority rule. As carried out in actual democratic politics, they see such behavior as deeply flawed. Democracy on their explicitly normative orientation ought centrally to encourage reasoned discussion and debate on the part of democratic decision makers in an open-minded spirit and equally possessing the information and other resources

productively to enter into deliberative forums before voting, if voting is needed at all. They do not deny that there are differences of interest and opinion among people but hold, in the optimistic manner of Rousseau, that given the opportunity to freely and equally discuss policy alternatives, they will sincerely strive to reach consensus.

Among the forums for deliberation are legislatures and courts, political parties, work places, unions and professional associations, social movements, and the media (Benhabib, 1996: p. 75; Gutman and Thompson, 1996: pp. 358–359). Deliberative democrats differ on what sorts of forums are the most important. They also differ on whether they see deliberative democracy primarily as strengthened liberal democracy or as a version of participatory democracy and civic republicanism, though many agree with Jürgen Habermas (1998: pp. 295–302) that deliberative democracy can bridge the divide between these orientations.

While placing different emphases on democratic deliberation as a procedure for making collective decisions or on the outcomes of deliberation, all deliberative democrats see the value of democracy undertaken in accord with their prescriptions as superior to simply aggregating preferences by voting. It at least leads to reasoned decisions, and it has the potential to shape the values of deliberators, in the manner of Rousseau's contractors, to ones aimed at promoting the common good. Democracy pursued in this way also is supposed by them to confer legitimacy on resulting policies lacking in what is often perceived by citizens as democratically unresponsive government (Benhabib, 1996; Manin, 1987).

Power-Political Pluralism

Deliberative democrats set themselves not just against the catallactic theorists but also against a kindred school also especially strong in U.S. political-scientific circles, the 'interest group,' or 'power-political' pluralists. The aspects of actual practices in modern democracies that these theorists take as their point of departure include voting, but they primarily focus on competition among the interest groups (labor, business, advocacy groups, etc.) that they see as the major actors in civil society. Robert Dahl, one of the leading representatives of pluralism in this sense, presented its basic principles in the form of a commentary (1956) on the Federalist Paper No. 10, written by James Madison (1751–1836).

According to Madison, the new American democracy was challenged by conflicts among those with different religious and political opinions and especially by class divisions based on "a landed interest, a mercantile interests, a moneyed interest," which have "inflamed them with mutual animosity" and "impeded cooperation for their common good" (1987 [1788]: p. 124). The check and balance system of federal government is defended by Madison as a way of preventing conflicts from becoming destructive of the whole society. Later pluralists added the encouragement of interest-group overlap, the nurturing of appropriate leadership, and reform of political institutions to regulate and contain conflict (Truman, 1951; Polsby, 1963). The main virtue pluralists see in democracy is its potential to keep the peace.

Radical-Democratic Pluralism

Whether deliberative-democratic measures could better address persisting conflicts is a matter of continuing debate. However, the pluralists, themselves, are in any case less concerned about conflict than their deliberative-democratic critics, since they view conflict as the natural human condition or even as 'democracy's lifeblood' (Lipset, 1960: p. 83). These views are echoed by a later version of pluralism based not on Hobbes-like political science but on contemporary, especially French poststructuralist philosophical views.

This is the orientation of 'radical-democratic pluralism.' Claude Lefort focuses on de Tocqueville's observation that in a democracy, rule is by 'the people as such' to argue that this makes the 'space' of democratic rule empty of identifiable rulers and opens the possibility for demagogues or populists to fill the space, claiming that they represent the will of the people considered in Rousseauean fashion as an ideal, homogenous entity (1988). Conflict in this perspective has no place in the space of popular sovereignty. Radical pluralists refer to this notion in criticizing the overriding value that deliberative democrats put on seeking consensus (Mouffe, 1993).

Societies are always composed of groups standing in relations of 'agonic' conflict with others. The challenge of democracy is not just to contain this conflict within peaceful limits, as is the goal with interest-group pluralists, but to prevent social agents (called 'subject positions' in keeping with the post-structuralist view that individual identities are always group-embedded and subject to change) from justifying domination over others on the grounds that they represent the true interests of a society. Rather than trying to replace conflict with consensus, the prime task is to recognize persisting conflict but to keep the space of democratic rule open. This, the radical-democratic pluralists maintain, is best accomplished by finding ways to integrate otherwise conflict-supporting identities with commitment to liberal democracy.

Issues and Problems

Most democratic-theoretical scholarship presupposes some view about the nature and value of democracy and concerns itself with specific issues and problems, three groupings of which are noted below.

The Boundary Problem

If democracy, whatever else it is thought to be, involves the idea that people have or ought to have some input to decisions that affect them, then it faces what Dahl saw as the insolvable 'embarrassment of democracy' that no matter where one draws a boundary around those who have input to democratic decision-making, some who are affected by the result will be outside this boundary (1982: pp. 97–99). For most of the history of democratic politics, this has been the case for women and usually also for those without property, that is, for a very large majority of those subject to democratic rule. In recent centuries, these exclusions have been eliminated as a matter of law, although feminist theorists and in general critics of systemic disadvantages argue that they and other exclusions

informally persist in all modern democracies (for instance, Young, 2000).

While almost every theorist agrees that exclusions based on such criteria as gender, wealth, or race are democratically illegitimate, there is less accord regarding other boundaries. Voting age varies from jurisdiction to jurisdiction, but no matter what it is fixed at, unless newborns are to have the vote, some people will be excluded. Similarly, noncitizen immigrants typically cannot vote, as this is seen as a privilege just of citizenship; but in some cities, recent immigrants not yet national citizens are granted the municipal franchise.

The most extensive current debate about democratic boundaries concerns states. Citizens in democratic states have access to means of intervention within those they inhabit, but, especially since the era of globalization, much of what affects their lives takes place outside of these states. So the problem is whether or how democracy can be extended across state boundaries. The strongest advocates of such extension are 'cosmopolitan' theorists who recommend trans-state institutions such as the European Union (Beck, 2000; the contributions to Held and McGrew, 2000).

Of course, such institutions do not completely solve the boundary problem unless the entire world is under single democratic rule. But aside from this consideration, other theorists maintain that it is unrealistic to extend democracy beyond state borders (Dahl, 1999) or that it is even undesirable if democratic institutions and practices are to be sensitive to the needs and values specific to people in individual states (Zolo, 1997). In response, yet other theorists look to increasing cross-state democracy, whether by coordination of associations of popular or social movement among them (Walker, 1993) or by a variety of international institutions short of world government (Saward, 2000).

Preconditions for Democracy

Most democratic theorists, beginning with Aristotle, devote at least as much attention to preconditions for achieving or sustaining democracy as they do to more abstract topics.

Culture

One question has to do with whether some sort of cultural 'glue' is required to hold citizens together in a democracy, and if so, of what kind. Mill maintained that democracy requires shared nationhood (1991[1861]), while disagreeing with him was Lord John Acton, who feared that this prompts national chauvinism (1995[1862]). Echoing Machiavelli and Hobbes, Rousseau thought that any enduring political regime, including a democracy, requires some form of religion to bind together its citizens (Beiner, 2011).

The general question here is whether there are specific cultural values – national, religious, or otherwise – that must be shared by a population if it is to sustain democracy. As approached in recent democratic theory, this issue was foreshadowed in the work of de Tocqueville, who saw cultural values particularly suited to democracy in the early American republic. The theme was later revived in empirical studies by Gabriel Almond and Sidney Verba about values that provide the sort of social cohesion they saw as vital for democracy (1963). Robert Putnam coined the phrase 'social capital' to describe cohesive cultural values, maintaining that paucity in social capital currently undermines U.S. democracy (2000).

Consociationalism

Consociational democratic theorists concern themselves with societies where there are major, largely regionalized religious or national divisions within a country (for instance, between Catholics and Protestants in the Netherlands or between Flemish- and French-speaking peoples in Belgium). Rather than seeing these divisions as insuperable threats to democracy, the consociationalists maintain that they can be contained by partial segmentation of political authority among the major groups while encouraging joint authority over matters of common concern and effective dialogue among segment leaders (Lipjhart, 1977). They therefore deny that thoroughgoing social cohesion is a condition for democracy, provided there are institutional means for regulating major divisions.

Democratic Consolidation

The issue of preconditions for democracy with respect to the developing world is central to theories of 'democratic consolidation.' Consolidation theorists usually take Dahl's concept of 'polyarchy' as definitive of democracy, where polyarchies are representative democracies with minimal restrictions on who can run for office; leadership depends on a universal vote; and citizens enjoy enforced rights of expression, access to politically relevant information, and freedom to join or form political or other associations (1989: p. 233). A democracy in this sense is consolidated when it is in no danger of reverting to a nondemocratic situation, when, as consolidationists put it, democracy in a country is 'the only game in town.'

Assuming that long-standing democracies in the developed world are safely consolidated, these theorists engage in empirical research with respect to developing countries and to those emerging from Communism to ascertain where and to what extent each is progressing toward consolidated democracy. The theoretical challenge of these endeavors is to identify the necessary or, in the most ambitious studies, also sufficient conditions for consolidation. Many consolidationists put primary or even exclusive emphasis on economic development (for example, Przeworski et al., 2000), while others look to blends of economic, political, cultural, and institutional factors (Diamond, 2008; Linz and Stepan, 1996).

One theoretical question raised in evaluating consolidationism is whether, as its advocates maintain, there should be a single list of characteristics of democracy, such as the components of Dahl's polyarchy, that pertain to all democratic societies no matter what their economic, cultural, and political features and histories. A related question is whether democracy should be seen as a matter of degree such that almost any society exhibits a mixture of democratic and undemocratic elements and there is no 'cutoff' point below which a society is simply undemocratic or above which it is as democratic as it can be. Orientations at variance with the consolidationists on these are expressed, among others, by the pragmatist, John Dewey (1927), and by Ian Shapiro (1999, Ch. 3).

Economic Systems

Related to the concerns of consolidationists, but of longer heritage and more prevalent before the demise of Communism in the Soviet Union than now, are debates over broad economic structures, specifically capitalism and socialism, as candidates for being conditions for democracy. Early perspectives on this question involved blanket judgments and had ideological rings to them. One example is von Hayek's assertion that "only within [capitalism] is democracy possible. When it becomes dominated by a collectivist creed, democracy will inevitably destroy itself" (1944: pp. 69–70). A contrasting claim is V.I. Lenin's announcement that socialism is "a million times more democratic than the most democratic bourgeois republic" in virtue of its being explicitly partisan in the interests of workers, while democracy in capitalism, according to Lenin, always serves the interests only of capitalists (1963–80[1918]: pp. 248–249).

There is a tendency in the extreme expressions to see capitalist or socialist economic structures not as empirical preconditions for democracy but to make them so by definition, thus cutting off nonideological debate. Less extreme treatments explore questions of how large-scale egalitarian policies by socialist or social-democratic governments can coexist with economic markets or avoid oppressive bureaucratization (examples are Bowles and Gintis, 1986; Schweickart, 1996). In recent years, approaches to these questions have been more empirical and have focused on the effects of economic inequalities in capitalist societies on democracy (e.g., by Gilens, 2012; Piketty, 2014).

Value Pluralism

Some theorists argue that, especially in an era of global-cultural interpenetration and multiculturalism, commitment to value pluralism is an essential component of democracy. Some think that democracy is at least severely stressed by multiculturalism (Glazer, 1983), while others see multiculturalism and democracy as compatible or even mutually reinforcing (Kymlicka, 1995). This debate joins a broader one about the desirability and the feasibility of value pluralism. Value pluralists champion toleration with respect to people's differing values. This orientation pertains for the most part to specifically liberal theory and practice, but it bears on democratic theory insofar as it prescribes against state paternalism and against the concomitant idea that a democratic state should itself promote a particular value-infused worldview.

Theorists in the tradition of civic republicanism not only challenge the notion that commitment to value pluralism is an essential part of democracy but see it as a threat to what they consider a properly conceived democracy. They hold instead that it is a primary obligation of a democratic state to imbue its citizens with the values of civic virtue (Beiner, 1992). Others, including some who place themselves within the liberal tradition, also hold that a democratic society ought to embody visions with values specific to them.

Mill announced the principle embraced by nearly all liberals since that "the only freedom which deserves the name is that of pursuing our own good in our own way" (2002 [1859]: p. 14). His rider is that restrictions are justified when some exercising this ability interfere with others doing likewise. (He also thought that the principle did not apply to 'backward states of society,': p. 12). Much liberal theory has subsequently occupied itself with the 'paradoxes' that arise from such value pluralism, as when deciding whether or how to be tolerant of intolerant values or how to deal with preferences about what the preferences of others should be (examples of contrasting approaches, in a vast literature, are Galston (1991) and Larmore (1987)). Democratic theorists confront similar problems. If a democracy does not legally enforce some moral visions or guiding moral norms and pursue compatible educational policies, then it could find itself sanctioning activities motivated by antidemocratic visions and norms and even in the end being undone by them.

John Rawls (1921–2003) attempts to solve this problem by distinguishing between 'political' values, such as support for civil liberties, and the 'comprehensive' values embodied in general worldviews, arguing that the first merit democratic state enforcement, while full toleration should reign in respect of the latter (1996). It is questionable whether this approach can deal with the problem posed to democracy and democratic theory by theocracy. This problem is to ascertain whether or how democracy, where ultimate authority at least over political matters rests in secular hands, can be reconciled with the theocratic principle that ultimate authority on all matters is divine. Debates on this question are currently most extensive among scholars of Islam over whether or how an Islamic state can be democratic. So, against the view of Samuel Huntington (1996) and others, Khaled Abu El Fadl argues that there is room for democratic values and politics within Islam (2002). (A survey of positions on this topic is in Hashemi (2009).)

Democratic Transitions

Abstract

Theories of democratic transitions focus mainly on domestic political and economic factors, though cultural and international factors are also addressed. Many hypotheses have been tested, increasingly using quantitative methods. Yet, the quest for robust positive results has proved elusive. Thus, current knowledge supports a negative funding that there is more than one path to democracy and that democracy can emerge under all sorts of conditions.

The study on democratic transitions began to take shape as a distinct field when researchers sought to make sense of the numerous cases of democratization that, from 1974 on, led to fundamental political change in all corners of the world. This literature, in contrast to the broader literature on democratization and democracy, focuses squarely on the critical step in the history of democracy when a country passes a threshold marked by the introduction of competitive elections with mass suffrage for the main political offices in the land. The seminal texts of this field are Rustow (1970), O'Donnell and Schmitter (1986), Przeworski (1991), Przeworski et al. (2000), and Linz and Stepan (1996).

Theories

Various families of theories of democratic transitions can be distinguished according to their emphasis on political, economic, or cultural factors – all understood as domestic factors – or on international factors. The most novel aspect of theorizing on democratic transitions starting in the 1980s is the attention given to *political* explanations, and the strategic choices of political actors, in contrast to the economism and sociologism of the dominant theories in the 1960s. Central to these new theories is the idea that splits within the regime or, more precisely, among the rulers who held power, lowers the cost of dissent, and opens the possibility of bargaining between reformist sectors of the ruling elite and moderate elements of the opposition. Relatedly, these theories reject the previously widespread view that there are some economic and cultural prerequisites of democratization, and hence that certain countries can be deemed to be not ready for democracy (O'Donnell and Schmitter, 1986; Przeworski, 1991).

A related strand of theorizing focuses on the political sphere but is more macro in orientation. Many scholars seek to explain democratic transitions in terms of features of nondemocratic regimes. This literature initially drew on broad typologies of twentieth-century regimes (Linz and Stepan, 1996: Chapters 3 and 4). But it has become more strictly institutional (Geddes, 1999; Gandhi and Przeworski, 2007; Teorell, 2010: Chapter 6), placing much attention on the so-called 'hybrid regimes' characterized by nondemocratic elections (Schedler, 2013); in some cases, though, the preferences of political actors are highlighted (Bellin, 2012). In addition, rekindling an old idea (Mazzuca, 2010), some scholars seek to theorize the impact of state formation and state capacity on the prospects of democratic transitions (Bunce, 1999; Wantchekon, 2004; Bratton and Chang, 2006; Tilly, 2007).

Alongside the theories spelled out in strictly political terms, scholars continue to pay attention to *economics*, focusing on economic actors, such as social classes, and on economic factors such as economic development, inequality, and performance. But unlike the classics of the 1960s (Lipset, 1960; Moore, 1966), the new economic literature does not consider politics only as an outcome and thus contributes to a political sociology and a political economy of democratic transitions. The political sociology of democratic transitions largely takes Moore (1966) as its point of reference but brings in politics through its attention to elites, the state, and social movements (Rueschemeyer et al., 1992; Collier, 1999; Tilly, 2007). In turn, the political economy literature draws on the Meltzer and Richard's (1981) median voter model of redistributive politics, which is used to derive predictions about the preferences of elites and masses for democracy in light of expected pattern of taxation and redistribution.

Some of the key debates take place within the political economy literature. Indeed, its common reliance on the median voter model notwithstanding, the political economic literature presents some divergent hypotheses. Some scholars see democratization as a concession by elites when the costs of democracy to the elites have been sufficiently reduced (Boix, 2003), while others see democratization as driven by elite efforts to curtail revolutionary threats from below and as entailing a real conquest for the masses (Acemoglu and Robinson, 2006). As a consequence, while some authors hypothesize that inequality and democracy are inversely related, others expect to find an inverted-U relationship between inequality and democracy. Relatedly, though scholars have emphasized that resources such as oil contribute to the endurance of nondemocratic regimes by reducing the demand for democracy while increasing the repressive capacity of autocrats (Ross, 2001), others suggest that oil raises the prospects of democracy in very unequal societies by reducing elite resistance to democracy (Dunning, 2008).

Beyond the literature that seeks an explanation of democratic transitions in the political and economic spheres, two less-developed literatures focus on cultural and international factors. Much of the literature that emphasizes *culture* takes Almond and Verba's (1963) classic as its point of reference and, as that work, usually sees politics as an outcome of culture,

understood in terms of attitudes and values, and ignores or downplays the possibility that politics shapes culture (Inglehart and Welzel, 2005). The literature on the links between religion, especially Islam, and democracy fits the standard cultural approach to democracy. One of the few exceptions to this approach is the literature on nationalism, which breaks new ground in that it emphasizes the various ways in which political choices and arrangement can make democracy viable in the context of multinational societies (Linz and Stepan, 1996: Chapter 2; Stepan et al., 2011). Overall, thus, much of the literature on culture and democracy can be questioned for offering a cultural approach to politics rather than a political cultural approach and for unjustifiably positing that culture is a prerequisite of democracy (Muller and Seligson, 1994; Przeworski, 2003).

Finally, a more recent literature addresses the impact of *international* factors on democracy. An older literature provides some clues about the impact of the geopolitical context on the origins of representative government and citizenship – though not on democracy per se – mainly through its effect on state formation (Hintze, 1975; Tilly, 1990: Chapter 4). But the literature of the 1960s and 1970s on economic dependency and world systems hardly contributed to a theory of democratization (Almond, 1989). Thus, an obvious gap is filled by a new literature that pays attention to the possible impact on democracy of the global economy, international diffusion, and external political influences. Some of the better-developed arguments link international factors to political economic explanations. For example, globalization is seen as contributing to democratization by making assets more mobile and hence reducing the threat of democracy to elites (Boix, 2003). But this literature, especially the strand on the array of activities that have as a stated aim the international promotion of democracy, is quite atheoretical, and there is little basis for the strong prescriptions offered by some authors regarding what Western governments should do and not do in the name of democracy (Schmitter, 2008).

Tests

Researchers have tested theories of democratic transitions in a variety of ways. But a marked novelty, since the late 1990s, is the increase of quantitative tests, usually using data on nearly all countries of the world from 1945 or 1972 onward but in some cases going back to 1800. All in all, scholars have devoted much time to assessing whether theories can postdict or explain the known course of events. Nonetheless, one overall conclusion of this research is that the quest for robust positive results has proved elusive.

The most thoroughly tested hypothesis, derived from modernization theory, concerns the impact of economic development, usually operationalized in terms of per capita income, on the prospects of democratic transitions as distinct from the endurance of democracy. Przeworski et al. (2000: Chapter 2) provide a key disconfirmation of this aspect of modernization theory, and Przeworski's finding is backed up by other statistical analyses (Acemoglu et al., 2008). But other authors challenge this finding (Boix and Stokes, 2003). Similarly, though some research shows that oil has a negative effect on democratization (Ross, 2001), other studies suggest that such a pattern holds only after 1980 and not in Latin America (Dunning, 2008; Ross, 2012: Chapter 3), and some researchers do not find an association between resource reliance and authoritarianism, and challenge the idea of a resource curse (Haber and Menaldo, 2011). Much the same can be said with regard to the inequality–democracy link. Some qualitative and quantitative studies support the idea that distributive politics is central to democratization (Tilly, 2004: 255, Przeworski, 2009) and hence question the theory that posits an inverse relationship between levels of inequality and democratization. But others suggest that the role of distributive politics is a common but far from universal feature of democratic transitions (Collier, 1999; Haggard and Kaufman, 2012). And yet others suggest that there is neither an inverse nor an inverted-U relationship between inequality and democracy (Houle, 2009).

Two comprehensive quantitative studies reinforce the view that robust positive results are hard to come by. A sensitivity analysis that considers over 50 possible explanatory factors and is based on some 1.7 million regressions with data from 165 countries from 1976 to 2002 concludes that only two determinants of democratic transitions are robust: GDP growth, which has a negative effect, and past transitions, which have a positive effect (Gassebner et al., 2013). In other words, most of the tested hypotheses are not confirmed. In turn, a quantitative study that tests a broad range of hypotheses using data on 165 countries from 1972 to 2006 concludes, "when the entire range of putative determinants is taken into account, [the] statistical models at best explain 10 percent of the yearly change in democracy" (Teorell, 2010: 10, 146–148). That is, the range of theories that are tested perform very poorly (for more detailed overviews of research findings, see Geddes, 2009; Schmitter, 2010; Teorell, 2010; Coppedge, 2012).

The failure to uncover global patterns does, however, provide indirect but strong support for a negative conclusion. Indeed, the accumulated empirical research does support the view (1) that there is more than one path to democracy (Rustow, 1970: 345, Collier, 1999; Tilly, 2004: 217) and (2) that democracy can emerge under all sorts of conditions (Przeworski et al., 2000: Chapter 2; Wantchekon, 2004: 17; Gassebner et al., 2013: 171). This is not a meaningless conclusion. It runs counter to common assumptions in the literature and oft-repeated arguments about democratic transitions. Moreover, it suggests that with regard to prediction – a challenge that is different from postdiction and explanation – the well-known failure of scholars to predict the collapse of communism in 1989 and the Arab Spring that began in the Middle East and North Africa in late 2010 is not just a reflection of the current state of knowledge. In all likelihood, the failure to predict these events is also due to the uncertainty that is inherent in political changes as momentous as transitions to democracy.

Challenges

Given the current state of knowledge, some suggestions can be ventured regarding challenges that need to be tackled, so as to ensure the continued development of research on democratic

transitions. First, because democratization entails a political change, it makes sense to look for explanations within the political sphere. However, because politics is not fully autonomous, it is also important to avoid a politicist approach and to consider interactions between politics and other spheres. This has been one of the strengths of the literature on democratic transitions. Yet, it is also clear that the strongest theory either focuses on politics or bridges the political and economic spheres. Thus, while it is critical to address the potential impact on democratic transitions of cultural and international factors, it is advisable to go about this task by building on the more developed theorizing in the political and political economy literature.

Second, though theorizing on democratic transitions has been fruitful, it has also been somewhat unstructured. Indeed, the fact that a comprehensive effort to test theories addresses some 60 hypotheses, each considered as equally important (Gassebner et al., 2013), suggests that something is wrong with the approach to theorizing used in this literature. Thus, future theorizing should be geared less to adding yet more hypotheses and more to embedding hypotheses in broad theoretical frameworks, developing theoretical syntheses, and formulating theory in a way that lends itself to more definitive testing.

Third, though many scholars have taken important steps to theorize political processes, most theories are largely a matter of macro-associations and most quantitative tests address conditions as opposed to actions. Thus, inasmuch as researchers seek to offer explanations, it is crucial that more emphasis is placed on causal mechanisms. And what this means is that theorists should focus on events and processes and formally propose testable hypotheses about causal mechanisms.

Finally, though the strengths of current tests should be recognized – the amount and rigorousness of tests has improved considerably over the past 15 years – so should the limits of these tests be noted. Many theories have not been tested. Thus, it is quite easy to make a case that most tests suffer from omitted variable bias; similarly, the possibility of reverse causation has not been thoroughly addressed. And many tests rely on poor data or poor data analysis. Yet, little has been done to rely on explicit criteria that would distinguish more credible from less credible results – the credibility of results is currently based on vaguely specified, informal criteria – and hence to distinguish theories that deserve to be further developed from theories that should be discarded. Indeed, in light of the explosion of empirical research, the need for criteria to identify credible results has taken on added urgency.

Demographic Impact of Disasters

Abstract

The frequency and magnitude of large-scale disasters in recent years has prompted increased interest in better understanding how major disruptive events alter key demographic processes. This article summarizes evidence establishing that disasters have significantly impacted mortality, health, fertility, and migration. While these processes are intimately interrelated, there have been relatively few integrative analyses that draw the evidence together, in large part because of inadequate data. Investment in population data collection systems to provide scientific evidence in the wake of disasters will broaden the depth and scope of disaster research, advance understanding of demographic changes, and inform policy interventions.

Introduction

The past decade has seen multiple large-scale natural disasters. These events, in combination with predictions that such events will increase in frequency as a result of global warming and rising population densities in vulnerable areas, have catalyzed interest in how affected populations respond to disasters, the effectiveness of emergency response programs, and whether emergency or longer-term assistance programs alter the life course trajectories of those affected by disasters.

Both disasters and recovery efforts have the potential to affect many outcomes of interest to social and health scientists. Accordingly, a wide array of disciplines has contributed to the study of disasters. We thus begin with a brief review of definitions of disasters and approaches to their study. This article focuses on the relationship between disasters and demographic phenomena. We therefore focus on mortality, fertility, and migration. These are three key demographic outcomes that are affected not only by disasters themselves but also by policies and programs implemented both before and after disasters.

The Study of Disasters

Disciplinary Approaches

Efforts to define disasters and use these definitions to shed light on various social, health, and demographic phenomena have a long history in the social sciences, particularly in sociology, geography, and epidemiology. Early sociological work on disasters focused on understanding collective behavior under high-stress conditions, taking the approach of dispatching researchers to stricken communities to observe postdisaster dynamics as they unfolded (Fritz and Marks, 1954). Although areas of emphasis have varied over the years, understanding how disasters strain social systems has remained a focus of this research (Quarantelli, 1989; Dynes et al., 1994; Klinenberg, 2002; Browning et al., 2006; Tierney, 2007). Within geography, efforts have centered more on the vulnerability of human physical systems to hazards (Gray et al., 2014) and on how to increase resilience of human systems, most frequently by studying one or a small number of communities. Disaster epidemiology provides timely assessments of the short- and long-term impact on health, broadly defined, and seeks to improve prevention and mitigation strategies (Guha-Sapir and Hoyois, 2012).

In many other disciplines, disasters are viewed through a broader lens. For example, in the economics literature, disasters are often treated as part of a more general class of 'shocks,' or unexpected changes. Shocks have been used to make inferences regarding the extent to which individuals are able to protect themselves, their families, and their communities from unexpected events with potentially adverse consequences (Townsend, 1994). A related literature exists in demography, although the focus is on demographic outcomes, and larger-scale macroevents with the potential to affect whole populations have received more attention (see, for example, Heuveline's innovative reconstruction of the Cambodian population after the Khmer Rouge regime) (Heuveline, 1998, 2001; Heuveline and Poch, 2007). Economic and demographic analyses have tended to prioritize representativeness at the population level and typically draw comparisons on a larger scale than geographic or purely sociological approaches. Finally, a large body of work in psychology and epidemiology examines the implications of disasters for various mental and in some cases physical health outcomes, most frequently through the analysis of survey data of varying degrees of representativeness (Armenian et al., 1998; Cao et al., 2003; Norris and Elrod, 2006).

Definitions of Disaster

Many definitions of disaster have been proffered over the years, generating a great deal of debate (Quarantelli, 1989, 2005). Most definitions recognize disasters as phenomena that arise from an unusually extreme precipitating event that is concentrated in time and space and that overwhelms local or, in some cases, larger-scale systems. Over time, definitions have increasingly recognized the importance of social construction on whether an event is interpreted as a disaster.

From a perspective based in sociology, Kreps (2001) defines disasters as "non-routine events in societies that involve conjunctions of physical conditions with social definitions of human harm and social disruption." Several important elements of this definition warrant highlighting. First,

according to this definition, disasters do not occur without people and the social systems they create. Second, chronic conditions, such as poverty, are not considered disasters. In some contexts, wars, genocides, famines, disease outbreaks, and weather-related events like floods, hurricanes, and tornadoes fit naturally into this definition. However, it is important to be precise about 'nonroutine.' In some parts of the world, these types of events have become all too routine. In those cases, it is necessary to appeal to an argument that the incidence may be routine but the precise timing or the severity of the event is not routine in order to apply this definition of a disaster. Alternatively, studies have treated the onset of such events as a disaster.

Disasters typically involve significant loss of resources and threats to – or actual loss of – life. The combination of these factors may result in a humanitarian crisis. Some studies have tried to classify precipitating events into various typologies, for example, whether they arise from environmental phenomena such as geophysical forces or weather, or from technical or willful actions. Sociologists' emphasis on understanding shifting social processes caused by disasters, beyond studying the catastrophic event itself, has resulted in the evolution of the set of events that are included within the rubric of a disaster, in particular as new findings related to social impacts have emerged (Herring, 2013). It is widely recognized that the interaction of the physical events with characteristics of the affected societies, such as the nature of housing and patterns of land use, plays a fundamental role in how disasters unfold.

Other important and distinguishing features that vary across disasters are the magnitude, scope and duration of the event, the degree of advance warning available to the population at risk, and the precision with which the event can be predicted. As an example, the 2004 Indian Ocean tsunami that hit the island of Sumatra, Indonesia, and Hurricane Katrina (that affected the U.S. gulf coast) were very different with respect both to whether the event was (or could have been) predicted and the amount of time that those likely to be affected had to prepare for the onslaught of the water. The tsunami hit some coastlines of Indonesia within minutes of the earthquake, whereas residents of New Orleans were warned about the approaching storm several days before Katrina made landfall (Munasinghe, 2007). Moreover, whereas hurricanes have been a part of the history of New Orleans since it was settled in the early eighteenth century, geological evidence indicates that there have been no tsunamis along the coast of Sumatra for over six centuries.

A Framework for Considering Disasters' Demographic Impacts

Demographers have examined disasters largely when their consequences occur at a scale with the potential to affect regional or national populations. Key parameters of interest are typically mortality, health, fertility, and migration, which, in turn, have implications for population size and composition.

The most dramatic link between disasters and demography arises in those disasters that cause substantial numbers of deaths. The risk of death in a disaster may vary by age and sex, reflecting differences in vulnerability across these dimensions as a result of physical differences or likelihood of exposure. Socioeconomic status may also be associated with risks of exposure such as when the poorest live in particularly vulnerable areas (such as flood plains) or when damage caused by the disaster depends on the quality of housing (as might be the case for earthquakes or tornadoes). In addition to immediate deaths, disasters may have longer-term or indirect effects on mortality through their effects on health status or its drivers.

Disasters also have the potential to displace people, either because people move preemptively or because the disaster affects their property or source of livelihood in ways that make remaining in the affected area unattractive or impossible. After disasters, displaced individuals may return, and others may move into the area, attracted by opportunities of various forms.

Though the mechanisms are less immediately obvious, disasters can also change fertility patterns. Disasters and the associated stress can affect coital frequency and potentially the ability to conceive a child or carry a pregnancy to term or they can change the demand for children. Disruption of services could also affect access to contraception. Disasters that result in large numbers of death may be followed by increased fertility. Finally, if the disaster changes the age and sex composition of the population as a result of mortality or migration, patterns of union formation may change in ways that alter fertility trends.

Several implications of the preceding discussion are worth drawing out in a little detail. First, although disasters typically begin with a precipitating event that can be pinpointed precisely in time, and often in space, temporal and spatial end points of disasters' impacts are not so cleanly delineated. Effects may be felt for a far longer time scale and over a far greater geographic area than that within which the disaster causes physical damage. A corollary is that the longer-term effects of a disaster may well reach far beyond those who were directly. For example, a disaster that affects the local area population composition may also affect the labor and marriage markets on a wider scale. Furthermore, a disaster that is followed by in-migration from other areas clearly affects not only the affected population and the migrants but also the communities from which the migrants have moved.

Second, the demographic processes we have discussed earlier are connected in myriad ways. To provide just a few examples, decisions to move are likely to be affected by household structure and decision-making processes which are, themselves, directly altered by mortality. Loss of kin and migration can affect stress levels, health, the desire for children, and the ability to conceive and bear children. Relatively few analyses consider these interlinkages, in part because few studies collect information on a broad set of potentially relevant behaviors and outcomes; fewer studies have successfully followed the trajectories of individuals, families, and communities affected by disasters over time.

Third, although we have emphasized the negative impacts of disasters, it is important to note that to the extent that disasters change opportunities, some of these changes may have positive consequences for individuals and communities. As disasters destroy land, housing, or infrastructure in one area, the value of comparable land, housing, or infrastructure is likely to increase. Disasters are often followed by reduced access to food and shelter: those who can provide food or

shelter are potential beneficiaries of this misfortune. In many cases, these are provided by governments or nongovernmental organizations as assistance. Indeed, assistance programs, themselves, may provide opportunities that change outcomes in positive ways as, for example, the programs buy food from local farmers. Other policy changes may affect longer-term outcomes and diminish the potential for known hazards to turn into large-scale disasters in the future. More generally, the policy environment can affect demographic phenomenon associated with disasters in significant ways.

High-Impact Disasters of the Last Decade

Before turning to evidence regarding demographic change in the context of disasters, we review the scope of disasters that have occurred over the last decade based on two indicators of impact, the death toll and the estimated value of property damage.

Table 1 summarizes impacts for the five disasters that are estimated to have had the highest number of deaths over the past decade (Panel 1) and the five disasters that are estimated to have had the greatest damage measured in financial terms (Panel 2). Of course, financial estimates of damage are, at best, rough; the table is intended to provide an illustration of the magnitudes that are involved.

With respect to mortality, the deadliest disaster was the 2004 Indian Ocean tsunami, which cost over 225 000 people their lives in Southeast and South Asia. The 2010 Haiti earthquake killed over 222 000, followed by Cyclone Nargis (138 366). Two other earthquakes, in China and Pakistan, caused tens of thousands of deaths as well.

With respect to property damage (measured in dollars of the year of the event), the earthquake and tsunami that hit Japan tops the list. Estimated property damages were approximately $US 210 billion, and Hurricane Katrina caused damages of $US 125 billion, according to data from the Center for Research on the Epidemiology of Disasters (CRED) at the University of Louvain. The 2008 earthquake in China is the only disaster that appears in both panels, which points to an interesting feature of disasters: the deadliest are not necessarily the costliest in terms of property damage. Instead, the highest costs have accrued in high- or medium-income countries, and in three of those disasters the numbers of deaths were quite low.

How such a table will look in a decade is unknown. On the one hand, if the various hazards mitigations and emergency preparedness policies that have reduced death tolls in industrialized countries can be implemented in a greater number of developing countries, death tolls from disasters may diminish. On the other hand, the size and density of populations in areas vulnerable to extreme geophysical or meteorological events is growing, which increases the number of people at risk of exposure.

The table is based on estimates aggregated to the national level. While useful as summary evidence regarding scale, the numbers shed little light on the full demographic impact of these events, let alone processes and mechanisms linking disasters to demographic change over the longer term.

Indeed, a major barrier to studying the demography of disasters is the relative scarcity of appropriate data. Many studies are based on relatively small-scale unrepresentative samples of individuals clustered into camps or other highly visible housing arrangements. Other studies use interviews of those who have remained behind in the affected areas. Typically, interviews are conducted once, shortly after the disaster. It is difficult to draw firm conclusions about the impact of the disaster on processes of population change with these types of data. The complexities of collecting population-representative data that characterize the periods both before and after the disaster, that span a continuum of destruction, and that follow movers to destinations other than camps have severely limited the representativeness of

Demographic Processes and Outcomes

In this section we review the evidence for linkages between disasters and various demographic outcomes.

Mortality and Morbidity

As shown in **Table 1**, disasters can cause loss of life on a massive scale. The extent of mortality caused by disasters varies depending on factors such as type of disaster, location, and timing. Counts of the dead and missing may not be accurate, and in some cases these rough estimates may not be finalized into an official death toll. Whether deaths have a meaningful impact on population size depends, in part, on the extent to which mortality is spatially concentrated. Mortality rates can help clarify impact, but their calculation requires information on the number of individuals exposed as well as the number dead – information that is not always available.

Risk of mortality may vary by age and sex in ways that differ across disasters. Several studies provide evidence that the Indian Ocean tsunami was associated with higher mortality for women than for men, and for the young and old. For example, based on a survey representative of pre-tsunami population, Frankenberg et al. (2011) show that mortality was lowest among men aged 20–44 years. Mortality rates were significantly higher for same-aged women, and higher still for children and teenagers, and for older individuals. It is likely that these differences reflect differences in strength and ability to swim since exposure to the tsunami is unlikely to vary by demographic group. Similar results are also reported for Sri Lanka following the 2004 Indian Ocean tsunami, where women and children experienced higher mortality compared to adults aged 20–29 years (Nishikiori et al., 2006).

These mortality patterns are unusual. They are not observed for the tsunami in Japan, where mortality was lower for school-age children than for individuals of other ages, and there are no significant differences in tsunami-related mortality between men and women (Nakahara and Ichikawa, 2013). Nor do they describe mortality in Haiti following the 2010 earthquake, where mortality was highest among those aged 18 and younger. In Haiti, about two-thirds of deaths were children younger than 12 years. Not only did children suffer higher mortality rates during the earthquake, they were also more likely to die from injuries and illness in the aftermath of the disaster (Kolbe et al., 2010). In contrast, mortality rates associated with Hurricane Katrina were highest among older adults (those 75 years or older), mostly due to these people not leaving the affected areas prior to the hurricane and ultimately drowning in the water (Brunkard et al., 2008).

Beyond mortality, disasters can affect health, with the nature of the impacts contingent on the characteristics of the event. Earthquakes often cause multiple injuries, including lacerations, fractures, contusions, chest and neurological problems, and potential cardiovascular issues (Bartels and VanRooyen, 2011). Health problems triggered by a disaster can continue in the long term. Residents of Louisiana and Mississippi experienced an increase in headache, nausea and digestive ailments, and respiratory and cardiac problems after Katrina (Adeola and Picou, 2012). Longer-term effects may be particularly important when the disaster creates additional health and environmental hazards, such as chemical, oil, or radiation spills.

The psychological, physical, and economic stresses associated with disasters can also affect birth outcomes for children born to women who are exposed while pregnant, and potentially these children's longer-term health outcomes. Evidence from offspring of women pregnant during the Dutch Hunger Winter indicates that extremely low caloric intake during the pregnancy results in reduced weight at birth, shorter stature as an adult, elevated risk of cardiovascular disease in midlife, and premature mortality. These results have been interpreted as being driven by the impact of the *in utero* nutritional insults through plausible biological pathways and have also implicated the postnatal nutrition environment (Stein et al., 1975; Ravelli et al., 1998, 1999; Roseboom et al., 2001; Rooij et al., 2010).

Several studies have explored the impact of natural disasters such as droughts or floods that occur *in utero* or in early life and established that these events can have effects that reach well into adulthood (Foster, 1995; Maccini and Yang, 2009). Other studies have investigated the impact of large-scale outbreaks of infectious diseases, most prominently, the 1918 influenza pandemic. Arguing the pandemic was unanticipated, Almond (2006) concludes that *in utero* exposure to the pandemic resulted in worse socioeconomic outcomes in adulthood relative to those surrounding cohorts that were not exposed. However, Brown and Thomas (2014) establish that the parents of the cohorts exposed to the pandemic were also of lower socioeconomic status relative to the parents of the surrounding cohorts, which complicates interpretation of the evidence. This highlights the general issue of the centrality of establishing whether a disaster is anticipated when interpreting the evidence. If the disaster is anticipated (or anticipatable), estimated effects likely reflect a combination of the impact of the disaster and potential behavioral responses in anticipation of the disaster.

Other studies have sought to investigate the relationship between stressful experiences during pregnancy and the physical health of offspring. These studies use quasiexperimental designs, drawing on some unexpected source of stress, such as acts of terror or war (Lauderdale, 2006; Camacho, 2008), an epidemic of crime (Brown, 2014), earthquakes (Torche, 2011), or hurricanes (Currie and Rossin-Slater, 2012). Using birth record data, they compare outcomes at birth of children *in utero* at the time of the event with outcomes of comparison children who were not exposed *in utero*. While the findings are consistent with the hypothesis that stress exposure affects birth outcomes, the estimated impacts are generally very small in magnitude and clinically unimportant. Moreover, many of the studies use large samples and the statistical significance of the estimated effects is not clear.

Morbidity after disaster extends beyond physical health. Studies in psychology and epidemiology have documented a number of systematic patterns of postdisaster mental health.

Studies assess a variety of specific and nonspecific psychological problems, but posttraumatic stress, depression, and anxiety are the most common ones regardless of the nature of the disaster (Norris et al., 2002; Norris and Elrod, 2006).

Relatively few studies are able to examine changes in psychological symptoms over time, but among those that do, most find that symptoms improve (Norris et al., 2002; Pietrzak et al., 2012). Data from the Galveston Bay Recovery Study (GBRS) show that individuals exposed to Hurricane Ike had symptoms consistent with PTSD, anxiety, and panic but that prevalence of these symptoms declined with time (depression remained stable across waves) (Pietrzak et al., 2012). Similar evidence has been reported for Indonesians affected by the Indian Ocean tsunami (Frankenberg et al., 2014).

Migration and Relocation

Migration, whether voluntary or impelled, is a potentially strong factor in reshaping populations after a disaster. In the context of disasters, population movements encompass temporary and permanent migration, both out of and into disaster-affected areas. Destinations can include unaffected areas (where the displaced may or may not have family or friends) as well as locations relatively nearby the impacted area where formal and informal camps may be established. But residents may also choose to stay where they were living at the time of the disaster, even if the area was badly affected, and new groups may move in, particularly if they perceive opportunities (most likely work-related) associated with relocating.

Migration decisions are affected by damage to the built and natural environment, among other things. Massive destruction displaces victims from their homes, potentially for extended periods of time. The 2010 earthquake in Haiti destroyed an estimated 24.4% of homes and damaged 41.5%. About 1.24 million Haitians were relocated to temporary settlements (Kolbe et al., 2010). Overall, it is estimated that Port-au-Prince lost 23% of its permanent residents.

Using an unusual methodology that relies on mobile phone data to study migration patterns in Haiti following the earthquake, Lu et al. (2012) analyze movements of 1.9 million phone users for up to 1 year after the earthquake. They show that shifts in location were more predictable than originally anticipated. Movements were closely related to patterns that predated the earthquake and were associated with location of social support networks.

Hurricane Katrina is another disaster that caused an almost unprecedented level of relocation of people in the United States, with some 1.5 million people emigrating from affected areas (Groen and Polivka, 2010). For residents of heavily damaged and low-income communities, opportunities to return to New Orleans were highly constrained by resource availability and the degree of destruction to their homes. Using a representative sample of pre-Katrina residents of New Orleans, Fussell et al. (2010) show that black residents experienced higher rates of housing damage, which often delayed their return to the city and contributed to reshape demographic characteristics postdisaster. Relying on data from the Current Population Survey, Groen and Polivka (2010) show that age, family income, and magnitude of damage at the county level significantly conditioned return of displaced populations even a year after the hurricane.

As discussed briefly earlier, some outcomes linked to disasters may have unexpected positive elements. Hurricanes Katrina and Rita caused massive migrations of students from low-performing to higher-quality schools. After an initial drop in median test scores, performance quickly recovered, and by 2009 median tests scores for movers rose by 0.18 standard deviations (Sacerdote, 2012).

Overall, Hurricane Katrina served to accelerate an ongoing reduction of the population of New Orleans (Zaninetti and Colten, 2012). In some cases, however, disasters do not result in significant population shifts. Using data collected from 291 tornado victims in Bangladesh, Paul (2005) shows that for the most part victims of this event decided to remain in affected areas, where they were likely to receive recovery assistance – an example of how postdisaster programs can generate their own demographic impacts.

Gray et al. (2014) compare mobility strategies among individuals living in small local areas that sustained different degrees of damage caused by the 2004 Indian Ocean tsunami in Indonesia. Those analyses call into question several common assumptions in the literature. For one thing, many individuals from heavily damaged areas did not move to IDP camps. More than half of the population either relocated to private homes or stayed in their community weathering adverse living conditions. Outside the heavily damaged zone, there was movement among individuals from areas relatively untouched by the tsunami, and regardless of origin area, mobility was higher for the better educated. These data underscore the likely value-added of studies that are designed to be population representative and capture both immediate impacts of disasters as well as responses to disasters over time.

Disasters can also attract new residents to damaged areas, especially if reconstruction efforts create employment opportunities. Given data limitations, it can be difficult to differentiate between returning and new migrants. Analyses of population structure of New Orleans after Hurricane Katrina show an increase in the percentage of Hispanic residents compared to predisaster levels (Groen and Polivka, 2010). Using census data from 2000 to 2010, Zaninetti and Colten (2012) estimate that the Hispanic share of the population in New Orleans increased by 57%, while the hurricane accelerated the decline of the black population. Latino immigrants took advantage of high demand of construction labor in the aftermath of Hurricane Katrina to relocate to New Orleans. Using a sample collected within 5 and 7 months after Katrina, Fusell (2009) shows that Hispanic immigrants moving to the area were younger and had weaker social networks and were often of Brazilian and Mexican origin.

Fertility, Reproductive Health, and Family Change

Disasters have the potential to affect fertility, reproductive health, and family change through a variety of mechanisms. Most proximately, high mortality disasters may change family composition. Adult deaths can leave young children without parents and create widows and widowers, who may or may not remarry. The 1958–61 famine in China is an example of an event that had significant consequences for family

demography. During the famine period, fertility and marriage rates declined, while divorce rates and family division increased (Zhao and Reimondos, 2012). It is not clear that the entire 3-year famine can be treated as unanticipated, which complicates interpretation of the results.

However, the Indian Ocean tsunami caused similar disruption to families. Using a population-based survey for Indonesia, Frankenberg et al. (2011) estimate that about 10% of children lost a parent and 10% of survivors lost a spouse. Deaths of children may leave parents with fewer offspring than they planned for and desire. On the other hand, when disasters cause high mortality, they are also likely to destroy assets and livelihoods, which may leave unmarried adults feeling less prepared to enter a union and couples feeling less prepared to provide for another child.

Even when disasters do not result in substantial mortality, they may prompt family change. Using a theoretical framework guided by work in psychology on stress and attachment, Cohan and Cole (2002) analyze rates of marriage, birth, and divorce before and after Hurricane Hugo, in affected and unaffected South Carolina counties. In counties declared disaster areas, rates for each of these outcomes rise and then fall. These changes do not occur in other counties, leading the authors to suggest that exposure to a life-threatening event prompted significant actions and measurable changes with respect to close relationships.

Potential changes to fertility can also be considered through a proximate determinants framework. Stress-affected populations may experience changes in coital frequency, rates of conception, miscarriages, and stillbirths. With respect to pregnancy outcomes, the Chinese famine resulted in a significant increase in stillbirths and miscarriages. By the end of the famine period, only 92% of pregnancies resulted in live births, down from more than 95% in 1958 (Zhao and Reimondos, 2012). Deterioration of physical health in the case of the famine also contributed to delays in reproductive development of young girls and reduced rates of breastfeeding (Zhao and Reimondos, 2012). Evidence from the 2004 Indian Ocean tsunami suggests that in the months following the disasters, rates of miscarriage rose for women from badly damaged areas (Hamoudi et al., 2012).

On the other hand, destruction of facilities and services may reduce access to contraception, leading to unintended births. Just as disasters destroy homes, shocks caused by disasters can create significant disruptions in infrastructure and complicate access to contraceptive supplies. Following the 2004 Indian Ocean tsunami, there were significant issues with health infrastructure (public and private health centers and midwifery). Frankenberg et al. (2014) show that for many communities disruptions in health facilities extended for at least a month and their reopening did not necessarily imply resumption in contraceptive supply. Midwifery services also suffered interruptions, in particular in communities where midwifes were among tsunami casualties.

Literature exploring empirical links between contraceptive availability after disasters and behaviors is limited. Some evidence shows disasters may result in the substitution from more- to less-effective family planning alternatives, with a resulting increase in unplanned births. In a retrospective study of 450 women in the aftermath of the 2006 earthquake in Yogyakarta, Indonesia, Hapsari et al. (2009) uncovered evidence of increased usage of less-effective contraceptive methods, which was accompanied by a subsequent rise in unplanned pregnancies in the year following the earthquake. Because the earthquake caused damage to over 200 health facilities, the authors conclude that shortage in access likely explains substitution of contraceptive methods. This evidence is consistent with studies that document increased fertility as a response to disruptions (availability, price) in contraceptive supply (Salas, 2013; Potter et al., 2013; White et al., 2012). In the case of service disruptions in Indonesia following the tsunami, Frankenberg et al. (2014) show lower uptake and higher discontinuation of family planning services among married women in heavily damaged areas. Changes in contraceptive usage were also predominant among women who desired more children; however, the authors do not find conclusive evidence of an increase in unintended fertility triggered by issues in supply of contraception.

Change in contraceptive use after a disaster may reflect changes in demand rather than supply. Loss of resources at the community and individual level may discourage couples from pregnancy and childbirth under precarious conditions (Carballo et al., 2005). On the other hand, child deaths may encourage parents to increase fertility, which, in turn, would reduce demand for family planning options (Preston, 1978; Zhu et al., 2013; Nobles et al., forthcoming).

In terms of linkages between demographic processes prompted by a disaster, the evidence base in the demography literature does not fully characterize fertility responses to large-scale mortality caused by disasters (Hill, 2004). Some of the best evidence comes not from disasters, but from wars and conflict. Decreases in fertility, either overall or for more- relative to less-affected subgroups, during conflicts accompanied by major social upheaval have emerged in a number of studies (Caldwell, 2004; Agadjanian and Prata, 2002; Blanc, 2004; Heuveline and Poch, 2007). In some instances, the end of the conflict is accompanied by a fertility increase. Famines are characterized by a similar temporal fertility pattern, as evidenced by studies from the Netherlands, China, and Bangladesh.

Relying on retrospective birth histories, Heuveline and Poch (2007) show a significant decrease in fertility during the years of the Khmer Rouge regime (1975–78), a sharp increase afterward (1978–80), and a subsequent decline. Based on this fertility pattern, the authors conclude that the significant increase in fertility was a direct response to heightened mortality during the conflict.

Isolating proximate mechanisms and disentangling whether fertility increases represent fundamental shifts in fertility desires or simply the realization of deferred reproduction are complicated when the precipitating events occur over multiple years and involve shifting spatial boundaries.

Nobles et al. (forthcoming) document similar behavior following the 2004 Indian Ocean tsunami in Indonesia. Using data from a population representative longitudinal study that includes observations before and after the 2004 Indian Ocean tsunami in Indonesia, they provide evidence of an increase in fertility between 2006 and 2009 in areas affected by the tsunami relative to unaffected areas. Two other studies explore fertility in the aftermath of high-mortality disasters. Finlay

(2009), using cross-sectional surveys, considers fertility for three earthquakes, each with death tolls of 15 000 or more. Comparing fertility before and after the earthquake for residents of areas affected by the earthquake with fertility of residents of areas that were not affected reveals greater postdisaster increases in fertility in affected areas. The same approach is adopted, with census data, to examine the impact of the 2003 Bam earthquake in Iran. The authors document a fertility decline in 2004, followed by a rise in 2005–07 (Hosseini-Chavoshi and Abassi-Shavazi, 2013).

Discussion

As discussed in the preceding sections, disasters have implications for the demographic processes of mortality, migration, and fertility, as well as for the linkages among them. The potential for feedback mechanisms among these processes is clear from a theoretical perspective, but relatively little empirical work has attempted to examine the interconnections and thereby test hypotheses about and provide a better understanding of the complex behaviors that underlie demographic processes. An exception is Heuveline's work on mortality and fertility in Cambodia during and after the decade marked by war and genocide (Heuveline, 1998, 2001; Heuveline and Poch, 2007). These investigations require data on multiple domains and behaviors of individuals, their families and, in many instances, communities that are collected over a time frame that is sufficiently long after the disaster for the behaviors to be revealed.

Unfortunately, such data are rarely available. Moreover, in the ideal world, the data would also be collected prior to the disaster although, as we have emphasized, disasters are in general unanticipated. However, creative investment in data infrastructure that exploits recent technological advances is likely to have a substantial payoff for science and policy. With the availability of high-quality satellite imagery, extensive administrative data sources, and population-representative longitudinal surveys being conducted on a regular basis across the globe, much of the key information needed to evaluate is already in place. In the case of the 2004 Indian Ocean tsunami, our international team of collaborators worked closely with Statistics Indonesia and followed up people who had been interviewed as part of the annual socioeconomic survey, SUSENAS, conducted about 10 months before the tsunami in all the districts along the west coast of Aceh and North Sumatra on the island of Sumatra. The 2004 SUSENAS served as the baseline for the Study of the Tsunami Aftermath and Recovery, which followed up the respondents annually for 5 years after the tsunami and then reinterviewed them again 10 years after the tsunami.

The demographic outcomes we have considered, as well as their interconnections, can be affected by policies and programs related to disaster preparedness and response. The development and enforcement of building codes, the creation of warning systems, evacuation plans, and temporary shelters, and well-trained first responders can alter the immediate consequences of disasters for mortality, health, and migration. Emergency assistance and longer-term recovery efforts can shape how outcomes unfold in a disaster's aftermath. The intersection of these policy and planning efforts with demographic phenomena has received relatively little attention in the literature to date. The questions are important, however, given the continued occurrence of major disasters and projected increase of people exposed to risk as a function of climate change.

Demographic Measurement: General Issues and Measures of Fertility

Abstract

The article explains the rationale for demographic measures and the principles of their construction. The difference between crude and specific rates is outlined. The main indicators used in the demographic analysis of fertility, including measures of both level and timing, are defined and set out in tabular form. Synthetic cohort indicators of fertility routinely used to summarize sets of period rates are described, and their advantages and disadvantages discussed. The arguments for and against tempo adjusted fertility indicators are outlined.

Introduction

Demographic measures are designed to quantify the level, timing, and distribution of demographic phenomena. Their purpose is to allow comparison across time and space, and between subpopulations. The need for measures arises particularly because the frequency of demographic events and states varies substantially by age; and because populations vary in size and composition with respect to age and other factors influencing the frequency of events and states. Measures may be crude – events per 1000 population, taking no account of population composition – or specific by one or more factors. Rates specific by individual attributes – age, marital status, urban/rural residence – are generally preferable to crude rates. Specific rates may be used to describe e.g., the age profile of demographic event rates, or may be summarized into a standardized single-figure index – such as a total fertility rate (TFR) or period life expectancy – using several forms of standardization.

General Overview

Demographic analysis employs measures of events, states, attributes, and cumulative experience. Classically, a core demographic activity consists in estimating the frequency of vital events, births and deaths, and of related events – migration, marriage and divorce, and, in more recent times, the formation and dissolution of coresidential unions. Other events studied in demography include conception, pregnancy, spontaneous and induced abortion, the use of contraception, leaving the parental home, household formation and dissolution, family changes such as transition to and from lone parenthood, and widow(er)hood. States of demographic interest include marital status, whether legal or *de facto*, type of family or household to which individuals belong, enrolment in education or training, migrant status, and so on. The classic attributes of demographic interest are age and sex, along with ethnicity, country of birth, and socioeconomic characteristics such as educational attainment and social class. Cumulative experience is examined using proportions of ever having experienced an event such as marriage, or estimates of the average number of a specified event experienced in a lifetime, or by a specific age, for example, the mean number of births by a particular age.

Events can be thought of as changes in state and, correspondingly, states can be considered to result from the occurrence and nonoccurrence of events. For example, the event of first marriage changes a person's marital status from single to married, and a person who has married and has not dissolved their marriage is currently married. In addition, the concepts of 'cumulative experience' and 'state' are to some extent interchangeable, for example, a woman who has had n live births (cumulative experience) is said to be of parity n (state) (the term *parity* relates to *women*). Measures of cumulative experience that do not refer to individual states are also used in demography, and these will be considered presently. The current entry does not cover methods of collecting and classifying demographic data, but is concerned with the use of data once it has been collected and processed, ready for analysis.

Demography is concerned in general with aggregate phenomena at the population level, where populations vary from global to local in extent. The units whose events and states are aggregated can be individuals, couples, families, or households. Some demographic measures are, however, strictly aggregate in type. These include the population growth rate, population density per unit area, or population dependency ratios, all of which are meaningful at the aggregate level only. Demographic measures focus on level, timing, and distribution: the frequency of events or prevalence of states (level), the age at or time between events (timing), and distributional aspects such as age structure or the geographical distribution of a population.

The need for demographic rates and other measures is readily stated. Counts of population or events are of demographic interest, particularly in an applied context, and are frequently the key input or output in a policy context. But absolute numbers, whether population size or numbers of vital events, are not sufficient for most analytical purposes. Population analysis is conducted in terms of the underlying phenomena – mortality, fertility, migration, and so on – that determine population change. For example, population projections are usually carried out by the component method, applying assumptions about fertility, mortality, and migration rates, rather than by extrapolating births, deaths, or population numbers. Rates, proportions, and other indices are required also for comparative purposes, whether tracking time-trends or making comparisons between (sub)populations. Spatially and temporally, populations vary in size and also in structure, and so measures that abstract from size and structure are required to compare the demographic metabolism, so to speak, of different populations.

Demographic rates and measures are numerous. The variety stems both from the widely varying forms in which data are

available and from the nature of the phenomena themselves. Data may come from vital registration systems, from population registers, from censuses and surveys, from parish registers, and other historical sources; or from administrative records. These sources may differ in the kinds of information recorded, in questions asked, and in details published. Fertility is the area in which measures are probably most numerous, a result of the complexity of the phenomenon: births are repeatable events, they can occur to women inside and outside of marital or cohabiting unions, their order in a birth history can be of significance, and they can be associated with several dimensions of personal time – age, union duration, duration since previous birth, and so on. (The term order relates to births. 'Order' is the order of a birth in a woman's fertility history. 'Parity' is the number of births a woman has already had. First births (births of order 1) occur to childless women, i.e., women of parity 0. Second births (births of order 2) occur to women who have had one birth previously, i.e., women of parity 1, etc. It is incorrect in English to refer to a 'parity 1 birth,' though such mistaken usage can be found in the literature.)

Rates, Probabilities, Proportions, and Ratios

A demographic rate expresses the number of events occurring relative to person years at risk of the event in a defined population for a specified time and place. It may be expressed per person year, per 1000 person years, per 100 000 person years at risk, and so on. The denominator, person years at risk or person years lived, is often estimated by means of the mid-year population or by the average of two end-year population figures, each of these being an approximation to the average population during the year. Francophone demography has specific terms to distinguish between two types of rates. In type 1 rates, the denominator is confined to those who are at risk of the event represented in the numerator (i.e., those who have not yet experienced the event but who could do so in principle). In type 2 rates, no such restriction is applied: the denominator may include people who have already experienced the event. Type 1 rates are known in English as occurrence-exposure rates. There is no specific term in general use in English for type 2 rates, though they are occasionally referred to as incidence rates or accumulation rates. A probability is the likelihood that an individual will experience an event. It is estimated by the number of events occurring during a defined period or at a particular age, to a specified group divided by the numbers of individuals present at the start of the period or age. A proportion is defined in the usual way, as the number with a given attribute at a given time point divided by the total population in question at that time. Finally, demographic measures also take the form of ratios, for example, the sex ratio at birth is the ratio of the numbers of male to female births. Ratios generally refer to aggregates, although anthropometric measurements in ratio form relating to individuals are also found in the medical demographic literature.

Crude Rates and Degree of Specificity

Demographic measures vary in their level of detail. The simplest are crude rates, expressed as the number of events per 1000 (or other multiple) of the total population, without any further specificity. The two most common are the crude birth rate (CBR) – the number of births per 1000 population in a year – and the crude death rate – the number of deaths per 1000 population in a year. They give basic information but do not allow refined analysis. Crude rates are of value in setting out the basic demographic parameters of a population and are used for descriptive purposes, particularly when the data needed for more detailed measures are either unavailable or unreliable.

Demographic rates and other measures are influenced by the composition of the population in respect of any factor by which the frequency of the phenomenon under study varies. Most importantly, crude rates are influenced by the age structure of a population, because of the association between age and demographic event rates, and also by sex composition, since demographic event rates usually vary by sex. Accordingly, specific rates may be calculated by placing conditions on the numerator or the denominator, or on both. Specificity may be introduced for one or more factors. For example, age-specific rates may be influenced by composition in respect of marital status, duration in a particular state, parity (number of children already born to a woman), urban/rural residence, and so on. So, the analyst might choose to calculate rates specific for a number of dimensions. For some purposes, variation according to specific factors may itself be the focus of interest. In other contexts, variation with respect to one factor (e.g., age) is taken as given and is not the subject of study. If so, the analyst will wish to remove the compositional effect from the comparison to be made. Traditionally, one of two procedures is used to remove the influence of such (nuisance) factors. Rates may be standardized for the factors concerned or may be disaggregated progressively so as to arrive at rates specific for internally homogeneous groups. Standardization may be through the conventional direct or indirect methods or by calculating a synthetic indicator of some kind (see Section More Complex Indicators below).

Both procedures have disadvantages. Standardization, whether by the conventional direct or indirect methods, or by constructing synthetic indicators, is well known to be valid only where there are no interactions between the factors for which the standardization is carried out, or when there are no interactions between them and the categories, populations, etc. to be compared. Since such interactions are often found, straightforward standardization is inappropriate in many instances. Progressive disaggregation of rates has the disadvantage of producing potentially large numbers of rates that are not readily summarized and perhaps not readily interpretable. Modern methods of model fitting can in many instances provide a more general and rigorous solution to the routine need for standardization in demographic analysis, and can offer a considerable advance on the progressive disaggregation approach. Hoem (1987) and his predecessors have shown that indirect standardization can be seen as a first step in an iterative estimation procedure for intensity regression based on a multiplicative hazard model.

Measures of Fertility

Basic Measures

Level of Fertility

The definition of the most common fertility measures is set out in Table 1. All of them may be calculated either on a calendar

Table 1 Selected measures of the level of fertility

Measure and time reference[a]	*Definition*[b]	*Notes*[c,d]
Crude birth rate (CBR) Period; cohort version also possible but rare	$\frac{B}{P} \times 1000$	B = number of births P = total person-years lived
General fertility rate[e] (GFR) Period; cohort	$\frac{B}{\sum_{15}^{49} W_x} \times 1000$	W_x = number of woman years lived at age x or in age group x
Age-specific fertility rate (ASFR) Period; cohort	$F_x = \frac{B_x}{W_x} \times 1000$	B_x = births to women aged x or in age group x W_x = woman years lived at age x or in age group x
Total fertility rate[e] (TFR) Period; cohort	$\sum_{15}^{49} F_x$	F_x is the age-specific fertility rate defined above. When rates are for 5-year age groups, the sum is multiplied by 5.
Age-specific marital fertility rate Period; cohort	$\frac{B_{x,m}}{W_{x,m}} \times 1000$	$B_{x,\ m}$ = births to married women at age x or in age group x $W_{x,\ m}$ = woman years lived while married and at age x or in age group x
Age-specific non-marital fertility rate Period; cohort	$\frac{B_{x,u}}{W_{x,u}} \times 1000$	$B_{x,\ u}$ = births to unmarried women aged x or in age group x $W_{x,\ u}$ = woman years lived while unmarried at age x or in age group x
Proportion of births that are non-marital[f] Period; cohort	$\frac{B_u}{B} \times k$	B_u = births to unmarried women during a year or period. The multiplier k may be 100 or 1000. The indicator may also be specific for age.
Age-parity specific fertility rate (type 1 rate) Period; cohort	$\frac{B_{x,i}}{W_{x,i-1}} \times 1000$	$B_{x,\ i}$ = births of order i to women aged x or in age group x $W_{x,\ i-1}$ = woman years lived while of parity $i-1$ and aged x or in age group x
Age-order specific fertility rate (type 2 rate) Period; cohort	$F_{x,i} = \frac{B_{x,i}}{W_x} \times 1000$	
Parity progression ratio Cohort; period version differs: see text	$a_i = \frac{\sum_{j=i+1}^{j=m} N_j}{\sum_{j=i}^{j=m} N_j}$	a_i = *parity progression of order i = probability of progressing from i-th to i + 1-th birth* N_j = number of women who have j births m = maximum number of births occurring
Gross reproduction rate[e] (GRR) Period; cohort	$\sum_{15}^{49} F_x^f$	F_x^f is The age-specific rate of female births. The sum is multiplied by 5 if 5-year age groups are used.
Net reproduction rate[e] (NRR) Period; cohort	$\sum_{15}^{49} F_x^f L_x^f$	L_x^f is The average number of person-years aged x in the stationary female life table with specified mortality, with a radix of 1.

[a]All measures given here relate either to a calendar year, time period, or cohort. For clarity, subscripts denoting the time reference are omitted, as most of the measures can be specified in either period or cohort form.
[b]The measures defined in female terms here can be defined analogously for men, but the male versions are rarely used. While summation is to 44 or 49 in a female index, summation could extend to later ages in male indices.
[c]In the specification of demographic rates, person-years lived, whether overall, or at a particular age or in a given state, is the true denominator. Where the rate relates to a year or period, events and person-years lived are those occurring during the year or period in question, at age x, where specified. A cohort rate is based on events experienced and person-years lived by the cohort concerned, at age x, where specified. Person years lived are normally estimated by the mid-year population.
[d]Throughout the table, age x denotes age x in completed years or, equivalently, age x at last birthday.
[e]When summation is over the reproductive ages, the lower limit of the summation is usually 15, but may also be 10, and the upper limit may be 44 rather than 49.
[f]This indicator was formerly known as the illegitimacy ratio.

period or on a cohort basis, though a CBR for a cohort is rarely seen. The article assumes throughout that period or cohort, data on births and population estimates are available. Where this is not the case, indirect methods for estimating population fertility parameters are available (*see* Demographic Techniques: Indirect Estimation).

The CBR is widely used in cross-national comparison, particularly since it requires relatively simple data – an estimate of total births and of total population. The general fertility rate is more specific, and restricts the denominator to those at risk of experiencing a birth, that is, women of childbearing age, usually 15–44 years or 15–49 years. Age-specific fertility rates introduce a further level of detail by age and are key indicators – they reveal both the level and the pattern of childbearing by age and are also the basis for calculating the total fertility rate, a widely used summary indicator described below. Age-specific fertility rates may be disaggregated further – by marital status, by duration of partnership or marriage, in place of or jointly with age, and by order of birth.

Fertility rates that are specific by order of birth are more precise and for many purposes more useful than the more widely available age-specific fertility rates. They are more informative about the nature of change through time because time-trends often vary by order of birth, particularly in modern contracepting populations or where the use of contraception is on the increase. Birth rates by order can be either type 1 or type 2 rates (see Section Rates, Probabilities, Proportion, and Ratios above). A type 1 (or occurrence-exposure) rate is more precise and restricts the numerator to births of a specified order, say order i ($i = 1,2, 3, \ldots$), and the denominator to women of parity $i-1$ ($i = 1, 2, 3, \ldots$), that is, only those women at risk of a birth of order i. Where age-specific also, this is known as an age-parity specific fertility rate: it is specific both by the age and the parity of the woman. Age-parity specific rates are conditional in the sense that they are conditional on the event not having

previously occurred. A type 2 order-specific fertility rate restricts the numerator to births of order i, but includes women of all parities in the denominator. For an age group, this gives the order-specific fertility rate for the particular age. To illustrate, suppose we have 1000 women aged 25–29 years in a particular year, 500 of whom are of parity 0 (childless) and 500 of parity 1 and above (women who are already mothers), and that 50 first births occur to these women during the year. The age-parity specific first birth rate at age 25–29 years is 50/500*1000 or 100 first births per 1000 childless women aged 25–29 years, per annum – a type 1 rate. The age-order specific first birth rate at age 25–29 years is 50/1000*1000 or 50 first births per 1000 women aged 25–29 years, per annum – a type 2 rate.

Both order-specific and parity-specific rates may also be specific by duration since marriage or start of union, or since some other event such as a previous birth (for second and higher order births), or since leaving education, or after arrival in a country of destination. A duration scale can either replace, or be combined with, age. Fertility rates specific by order of birth based on vital registration data will be inaccurate wherever, as sometimes occurs, the order of birth as recorded in a particular system is not based on the woman's complete birth history; population registers or survey retrospective fertility histories are an alternative source.

Fertility rates may vary by parity, and in modern contracepting populations always do so. Because any given overall level of fertility may be reached through differing patterns of parity-specific fertility, measures known as parity progression ratios (PPRs) were developed in the early 1950s. They represent the probability of making each transition in the family building process. The PPR of order i, a_i, is defined as the probability of proceeding from parity i to parity $i+1$. It can be obtained as the proportion of women of final parity i and above, who, by the end of childbearing, have had at least $i+1$ births. Here $i = 0, 1, 2 \ldots m-1$, where m is the maximum number of births to any woman in the population. These ratios express, in other words, the probability that a woman who has had a given number of live births, will have at least one further birth. In their original form, PPRs are calculated on a cohort basis but they are meaningful for any group of women aged 45 years plus. Methods for estimating these for women who have not reached the end of childbearing have also been proposed (Brass and Juarez, 1983).

Timing of Fertility

The principal measures of fertility timing are set out in Table 2. They are somewhat less numerous than indicators of fertility level. The mean and median age at birth are the most basic factors. Somewhat more precise is the mean or median age-specific by order of birth; mean or median age at first birth; at second birth; and so on. Mean and median ages may be obtained from either period or cohort data, and as with measures of the level of fertility, time series of these will generally differ. Whether or not specific by order, the period mean or median age at birth can be calculated in crude or standardized form, and published sources do not always indicate which of these is presented. The period crude mean age at birth (or at first birth, second birth, etc.) is obtained simply as the arithmetic mean age of all women having a (first, second, etc.) birth in a given period. The crude mean age at birth is widely used but has the disadvantage, in

Table 2 Selected measures of fertility timing

Measure and time reference[a]	*Definition*[b]	*Notes*[c]
Mean age at birth (crude) Period; cohort	$\frac{\sum_{15}^{49} xW_x^b}{\sum W_x^b} + 0.5$	W_x^b = the number of women aged x last birthday having a birth Where age is grouped, x = mid-point of each age group
Standardized mean age at birth Period	$\frac{\sum_{15}^{49} xF_x}{\sum_{15}^{49} F_x} + 0.5$	Where age is grouped, x = mid-point of each age group
Median age at birth (crude) Period; cohort	Median age of women having a birth in a period or, within a cohort, median age of women at childbirth	
Standardized median age at birth Period	Median of the age-specific fertility distribution	
Mean age at i-th birth (crude) Period; cohort	$\frac{\sum_{15}^{49} xW_{x,i}^b}{\sum_{15}^{49} W_{x,i}^b} + 0.5$	W_x^b = women aged x last birthday having a birth of order i Where age is grouped, x = mid-point of each age group
Standardized mean age at i-th birth Period	$\frac{\sum_{15}^{49} xF_{x,i}}{\sum_{15}^{49} F_{x,i}} + 0.5$	$F_{x,i}$ = age-order specific birth rate of order i, during a year or period (defined in Table 1)
First birth interval		
Cohort; for synthetic period version, see text	Duration from marriage (or start of union) to first birth	Less useful where moderate to high proportions of first births occur outside of a union
Second, third, etc. birth interval Cohort; for synthetic period version, see text	Duration from first to second birth, second to third birth and so on	Caution: Cannot be calculated from the mean ages at births of each order, unless specifically for women with $i+$ births; see text.

[a]All measures given here relate either to a calendar year, time period, or cohort. For clarity, subscripts denoting the time reference are omitted, as most of the measures can be specified in either period or cohort form. In a period index, events relate to those occurring in the year or period, at age x where specified. In the cohort case, events are those occurring to members of the cohort concerned, at age x where specified.
[b]The measures defined in female terms here can be defined analogously for men, but the male versions are rarely used.
[c]Throughout the table, age x denotes age x in completed years or, equivalently, age x at last birthday.

a period context, of being influenced by the age structure of women of childbearing age, which can vary through time and from one country to another. Far better for the purposes of period analysis, although more demanding of data since population denominators are required to calculate age-specific rates, is the standardized mean age at birth, or at first birth, second birth, and so on. Standardization is unnecessary in a cohort framework, which is self-standardizing, although care should be taken in comparisons of cohorts widely differing in mortality during the childbearing years. The standardized mean age at birth is obtained by weighting by the relative period age-specific fertility rates at each age (see **Table 2**) and so is, in fact, the mean of the age-specific fertility distribution. Similarly, the standardized mean age at *i*-th birth uses as weights, the relative age-order-specific fertility rates (type 2, not type 1 rates). The standardized mean age at birth is not a pure measure of fertility timing since it is influenced not only by timing but also by the overall level of fertility. If populations A and B have identical (standardized) mean ages at each order of birth but if proportionately more women in A than in B have births of higher orders, the standardized mean age at birth will be older in A than in B. The mean age at last birth is occasionally used in historical demographic literature as an indirect indicator of the presence of birth control. It can be calculated, without bias, only for women who have reached the end of reproduction (age 45 or 50 years).

Fertility tempo is also measured by the mean or median duration of birth intervals. The first birth interval is the time from marriage, or start of informal union, to the first birth. This interval may be of limited utility where a large proportion of births occur outside of formal or informal marital unions. Later intervals are obtained as the duration from first to second birth (second birth interval), from second to third birth (third birth interval), and so on. Some care is needed in measuring such intervals. Mean birth intervals are sometimes estimated erroneously from the ages of women at births of successive orders of birth. This is incorrect because the ages at successively higher orders of birth are based on women of differing ultimate family sizes. The difficulty arises because women who ultimately have larger families are usually younger at births of any given order than are those with smaller completed families. The *i*-th birth interval is calculated instead as (1) the time from birth $i-1$ (or start of union where $i = 1$) to birth i among women with i or more births, or equivalently as (2) the age at birth i minus the age at birth i-1 (or at the start of union when $i = 1$) among women with i or more births. Where individual level data are available, means or medians may then be calculated. The median may be preferred to the mean birth interval, since birth interval distributions are typically positively skewed. Synthetic or hypothetical mean or median birth intervals for time periods may be obtained from the life tables used in constructing PPPRs (see Section Period Parity Progression Ratios below), thus giving a period measure of birth timing analogous to, and supplementing, the standardized mean age at birth (Ní Bhrolcháin, 1987).

The mean length of a generation is of importance in stable population theory. It is defined as the time it takes a stable population to grow by the factor net reproduction rate (NRR). It is represented in stable population theory by the symbol T and is given by $T = (\ln NRR)/r$, where r is the intrinsic growth rate of a stable population (*see* Preston et al., 2001; Population Dynamics: Theory of Stable Populations).

More Complex Indicators

The TFR and Associated Indices

Since a set of specific fertility rates for a period can be numerous, single-figure indices that summarize them are convenient and often a practical necessity. The classic method of condensing them is the synthetic or hypothetical cohort indicator. A period synthetic cohort indicator is obtained in one of two ways: by summing age-specific rates (type 2) across ages, or by combining occurrence-exposure rates (type 1) multiplicatively across ages in a life table calculation. The most widely used synthetic indicator in the fertility arena is the classic period TFR, obtained by adding the age-specific fertility rates of a given year or period across ages 15–49 years. The most familiar example of the multiplicatively produced synthetic indicator is period life expectancy (*see* Demographic Measurement: Nuptiality, Mortality, Migration, and Growth). The TFR is routinely interpreted as representing the mean family size in a hypothetical cohort of women who experienced the age-specific fertility rates of the period in question throughout their childbearing years.

Closely related to the classic TFR are the gross reproduction rate (GRR) and the NRR. The GRR is simply the TFR confined to female births, and can be seen as the average number of daughters a woman would have if she experienced the age-specific female birth rates of a particular period. The NRR is obtained by modifying the GRR to take account of female mortality up to the end of the reproductive age range (see **Table 1**). It can be interpreted as the average number of daughters who would be born to a newly born cohort of girls in a stable population in which age-specific female fertility and mortality rates remain fixed (see Population Dynamics: Theory of Stable Populations). In a theoretical, stable population, the NRR represents the extent to which generations replace themselves. Under stable conditions, an NRR of <1, 1, or >1 means that successive generations are, respectively, declining, stationary, or growing in numerical size. The GRR is roughly half the size of the TFR. The NRR is less than the GRR, the gap between them depending mainly on the level of female mortality at ages under 50 years: the higher the level of mortality, the greater the disparity between the GRR and the NRR. The TFR, GRR, and NRR can also be specified on a male basis, using male age-specific fertility rates and male survivorship, and the results will in general differ from the female values. Female rates are, however, more widely available and more reliable and are used universally; however, male rates are used when a specific focus is on male fertility or in theoretical work.

Difficulties with the TFR

A key advantage of the TFR is that it is standardized for age and that it is relatively undemanding of data. But it has shortcomings as a measure. A theoretical difficulty with the TFR and with synthetic cohort indicators in general, is that they express period events in terms of lifetime experience. Mean family size is conceptually meaningful for a cohort but the mean family size of a period has no concrete meaning (Ní Bhrolcháin, 1992). The synthetic cohort interpretation can be avoided by thinking of

the TFR as a convenient summary of the level of a phenomenon in a particular period. Nevertheless, the difficulty remains that time-trends in fertility are not homogeneous among those at risk, but can vary by parity, by age, and by duration. No single-figure indicator can accurately represent the multiple dimensions of change. Finally, the TFR is highly subject to variations in the timing of childbearing. When the pace of childbearing is accelerating, the period TFR is above the corresponding cohort mean family sizes, and when the pace is decelerating, the period TFR falls below the associated cohort values. The TFR is more volatile than the comparable cohort series for two main reasons: it takes no account of the past fertility experience of the women at risk at a particular time and, relatedly, it is not standardized for the parity distribution of the population at risk. The TFR of a given period is influenced both by the behavioral parameters of the period and by the impact of the fertility of previous years on the distribution of exposure in the period.

One time-honoured solution, due originally to Hajnal (1947), is not to rely exclusively on period analysis to interpret trends but to use cohort fertility in conjunction with period information: cohorts, he suggested, are the best guide to long-run trends and parity-specific period indicators better describe recent and current trends. Further approaches to handling the shortcomings of the classic TFR are described in the two sections that follow.

Period Parity Progression Ratios

The period parity progression approach to fertility measurement is an alternative to the classic TFR, and goes a long way toward addressing the sensitivity of the TFR to changing tempo. The period parity progression ratio (PPPR) is defined for each order of birth. It is a synthetic indicator representing the PPR that would result if a cohort were to experience during their lifetime the parity-specific, duration-specific, and/or age-specific birth probabilities of a particular period. An indirect method of estimating these is due originally to Henry (1953, translated 1980) and a direct method to Ní Bhrolcháin (1987). The PPPR is calculated by cumulating parity specific rates (type 1) multiplicatively, in life table format, for each order of birth. The parity specific rates may be specific by duration, by age for first birth and duration for later births, by age alone, or by both age and duration (Ní Bhrolcháin, 1987; Murphy and Berrington, 1993; Rallu and Toulemon, 1994). PPPRs largely correct for differences in composition resulting from past experience and have the advantage also that they do not produce results that would be impossible in a true cohort. The PPPR approach improves on the classic TFR not only in standardizing for parity and in removing tempo effects, but also in measuring multiple facets of the fertility of a given period, and in providing multiple indicators of time-trends.

The PPPRs can be used to obtain an estimate of the period TFR that is alternative to the standard TFR, generated as

$$\mathrm{TFR(PPPR)} = a^p_{0,t} + a^p_{0,t} \times a^p_{1,t} + a^p_{0,t} \times a^p_{1,t} \times a^p_{2,t} + \cdots + a^p_{0,t} \times a^p_{1,t} \times a^p_{2,t} \times \cdots a^p_{m-1,t}$$

where $a^p_{i,t}$ is the PPPR of order i for period t, and m is the maximum number of births occurring. The TFR (PPPR) has the advantage over the conventional TFR that it is standardized for parity and also removes much of the timing influence to which the classic TFR is subject. Like the classic TFR, however, it is a one-dimensional measure.

Tempo Adjustment

The decades since the 1970s in developed countries have been marked by very substantial shifts to later ages at childbearing. The result is a sizable downswing in the TFR that has made it even less trustworthy than usual as a guide to longer-run fertility levels. And while the period parity progression approach provides a useful counterweight to tempo shifts, it is fairly demanding of data, requiring parity specific rates by age and/or duration. One methodological response is to attempt to remove the influence of tempo change from the TFR and so produce a tempo adjusted TFR, denoted as TFR* (Bongaarts and Feeney, 1998). The approach has been much discussed, and has been developed further in a number of directions (Kohler and Philipov, 2001; Kohler and Ortega, 2002; Ediev, 2008). Demographic opinion remains divided on the case for and utility of tempo adjustment. Difficulties with tempo adjustment include lack of parity specificity of the TFR*, erratic behavior of TFR* under realistic theoretical scenarios of change, lack of evidence validating tempo adjusted measures as estimators of underlying cohort values, and that the tempo component is integral to period fertility measures where the aim is to explain either period change or cross-national differences (Lesthaeghe and Willems, 1999; Van Imhoff and Keilman, 2000; Schoen, 2004; Ní Bhrolcháin, 2011). If the objective is to seek accurate and efficient estimators of the final fertility of cohorts that have not yet completed their childbearing, relying on tempo adjustment alone is limiting. Recent approaches move away from using tempo adjustment to characterize a particular period's fertility, and instead adopt a broader framework aiming explicitly to estimate the completed fertility of cohorts (Cheng and Lin, 2011; Cheng and Goldstein, 2012). This alternative strategy appears to be promising.

Demographic Measurement: Nuptiality, Mortality, Migration, and Growth

Abstract

This is the second of two articles on demographic measurement, the first article being entitled *Demographic Measurement: General Issues and Measures of Fertility*. This second article presents the principal ways in which nuptiality, mortality, migration, and population growth are currently measured in demography. The section on nuptiality covers indices of both level and timing of marriage, divorce, and cohabitation. Crude and specific rates are presented along with synthetic or hypothetical cohort measures. The definitions of the main types of nuptiality and mortality measures are given in tabular form.

Introduction

In the article *Demographic Measurement: General Issues and Measures of Fertility*, we saw that demographic measures are required for comparisons through time and space, and between subpopulations. Well-specified measures are needed because the rate of demographic events varies both with age and with other dimensions of personal time, and because populations vary in size and in composition with respect to age and other factors influencing demographic event rates. Type 1 and type 2 rates were distinguished. In type 1, or occurrence-exposure, rates the denominator is confined to people who are at risk of the event in question. In type 2 rates, no such restriction is placed on the denominator. Synthetic or hypothetical cohort measures were introduced, their purpose being to summarize an array of specific rates pertaining to a period and to estimate the hypothetical lifetime consequences of the set of rates obtaining in a calendar period. Some demographic indicators measure 'flow' – the movement into and out of the population or into particular states – whereas others measure the 'stock,' or cross-sectional state of the population at a given time. Some further types of demographic behavior are considered in this article.

Marriage, Cohabitation, and Union Disruption/Divorce

Indicators of marriage and divorce are much less numerous than those of fertility. Measures of both level and timing are considered here.

Level

The most basic of the 'flow' indicators are the crude marriage rate, defined as the number of marriages per 1000 population, and the general marriage rate, defined as the number of marriages per 1000 population of marriageable age, usually 15 years of age and above, but the legally allowable minimum age at marriage varies between countries (**Table 1**). These rates are influenced both (a) by the structure of a population by age and sex, since marriage rates vary by age and sex, and (b) by the proportions currently married, since those already married are not at risk of a further marriage (though would be so if they were to divorce). To deal with the second of these, a general marriage rate may be defined per 1000 unmarried persons. Age–sex variation in rates is handled in the conventional way by defining marriage rates specific by age and sex. Age–sex specific marriage rates may be refined by restricting the denominator to the unmarried. Further detail may also be introduced by calculating marriage rates specific by order of marriage. Thus, in an occurrence-exposure rate of first marriage (type 1), the numerator of the age–sex specific first marriage rate is confined to first marriages and the denominator is restricted to people who are single (i.e., never married). A type 2 rate of first marriage has the same numerator as the type 1 rate, but the denominator includes all persons in the age–sex group in question. Remarriage rates are generally of type 1, i.e., they express the number of remarriages, by age and sex, per 1000 divorced and widowed persons, but they too can be calculated in type 2 form – remarriages per 1000 persons in an age–sex group, irrespective of marital status. All rates may be calculated on either a period or a cohort basis. The crude and general marriage rates can be standardized for age, using conventional standardization methods.

As an adjunct to, or sometimes in place of, period or cohort marriage rates, the cross-sectional distribution of marital status by age and sex may be used to depict the nuptiality of a population. These are 'stock' figures and have the advantage that they can be obtained from any census or survey in which individuals' current marital status is recorded and so do not require vital registration information or annual population estimates by age and sex. They reflect the prevalence of marriage, divorce, and widow(er)hood resulting from past rates of marriage and marital dissolution, and so do not represent marriage rates, etc., in the population concerned. However, marriage rates in preceding years can be reconstructed from cross-sectional surveys if information on retrospective marriage histories is collected.

Measuring the frequency of nonmarital cohabitation and of other types of informal partnerships is in principle similar to marriage but less straightforward. This is both because vital registration data are not available and because cohabitation and marriage behavior may need to be considered jointly, for a full picture (see Murphy, 2000 for a discussion of some methodological issues). Because informal partnerships are not recorded in vital registration systems, and that population estimates by *de facto* marital status are not usually available, the traditional approaches to measuring marriage often cannot be adopted. Table 1 Selected measures of marriage

Measure and time reference[a]	*Definition*	*Notes*[b,c]
Level		
Crude marriage rate		
Period	$\frac{M}{P} \times 1000$	$M =$ number of marriages during a specified year or period. $P =$ total person-years lived.
General marriage rate		
Period	$\frac{M}{P_{15+}} \times 1000$	$P_{15+} =$ person-years lived at ages 15 and above
Age–sex specific marriage rate (type 2)		
Period; cohort	$N_x^f = \frac{M_x^f}{P_x^f} \times 1000$	$M_x^f =$ women marrying at age x or in age-group x. $P_x^f =$ woman-years lived at age x or in age-group x. Analogous definition for men.
Age–sex specific first marriage rate (type 2)		
Period; cohort	$\frac{M_{x,1}^f}{P_x^f} \times 1000$	$M_{x,1}^f =$ single women marrying aged x or in age-group x. Analogous definition for men.
Age–sex specific first marriage rate (type 1)		
Period; cohort	$\frac{M_{x,1}^f}{P_{x,u}^f} \times 1000$	$P_{x,u}^f =$ woman-years lived while single and aged x or in age-group x Analogous definition for men.
Total marriage rate		
Period	$\sum_{15+} \frac{M_x^f}{P_x^f}$	Where age is in 5-year groups, the sum is multiplied by five. Analogous definition for men.
Total first marriage rate		
Period	$\sum_{15+} \frac{M_{x,1}^f}{P_x^f}$	Where age is in 5-year groups, the sum is multiplied by five. Analogous definition for men.
Gross nuptiality		
Period; cohort	$1 - \prod_{x=15+} (1 - q_x^f)$	$q_x^f =$ probability that a single woman aged x exactly will marry before $(x+1)$th birthday. Age range used may vary. Analogous definition for men.
Net nuptiality		
Period; cohort	Cumulative proportions ever marrying in a double-decrement life table with marriage and mortality as decrements	Age range used may vary. Defined for males and for females.
Timing		
Mean age at marriage (crude)		
Period; cohort	$\frac{\sum_{15+} xM_x^f}{\sum M_x^f} + 0.5$	Analogous definition for men.
Mean age at marriage (standardized)		
Period	$\frac{\sum xN_x^f}{\sum N_x^f} + 0.5$	Analogous definition for men.
Singulate mean age at marriage		
Period	$15 + \frac{\sum_{15}^{49} S_x^f - 35S_{50}^f}{1 - S_{50}^f}$ Assuming no marriage before age 15	$S_x^f =$ the proportion of women aged x who are single. S_{50}^f can be estimated by the mean of the proportions single in age-groups 45-49 and 50-54. Where 5-year age-groups are used, the first term in the numerator is multiplied by 5. Analogous definition for men.

[a]All measures given here relate either to a calendar year, time period, or cohort. For clarity, subscripts denoting the time reference are omitted.
[b]In the specification of demographic rates, person-years lived is the true denominator. Where the rate relates to a year or period, events and person-years lived are those occurring during the year or period in question, at age x where specified. A cohort rate is based on events experienced and person-years lived by the cohort concerned, at age x where specified. Person-years lived are normally estimated by the mid-year population.
[c]Throughout the table, age x denotes age x in completed years or, equivalently, age x at last birthday.

cross-sectional censuses and surveys are therefore a primary source of information. The absence of good quality information on informal unions limits assessment of levels and trends in *de facto* unions particularly in developed nations, where the prevalence of cohabitation has increased substantially since the 1970s, and in some countries of the Caribbean and Latin America, where visiting or consensual unions have long been common (Fussell and Palloni, 2004). Among the indicators used to evaluate the frequency of informal unions are: the proportion currently cohabiting, the proportion who have ever cohabited, the proportion cohabiting with their marriage partner prior to marriage, and the proportion of current unions that are cohabiting unions. The frequency of informal unions evaluated by all of these indicators tends to vary with age, and social differentials can vary both with age and the measure used (Ni Bhrolchain and Beaujouan, 2013).

The crude divorce rate is analogous to other crude rates, being defined as the number of divorces per 1000 persons in a population. It is influenced in a compositional sense by the proportions married by age and sex, and by the distribution of marriages by duration, since divorce rates are closely tied to duration of marriage. Where data are available, a slightly more detailed measure is preferable: divorces per 1000 existing marriages in a population. As with other events, divorce rates are more informative if specific by age and sex: divorces in an age–sex group per 1000 married persons in that age–sex group. However, divorce rates specific by duration of marriage are usually preferred to age-specific rates since divorce risk varies substantially by marriage duration. Divorce rates specific by both age at and duration of marriage, as well as by sex, are especially informative since the risk of divorce is strongly related to age at marriage, being higher among those marrying at younger ages. The divorce rate is sometimes expressed, mistakenly, as the number of divorces in a year per 1000 marriages in that year. This is erroneous because the divorces in a given year stem from marriages that took place in preceding years, and so divorces should be related in some way to the stock of marriages that are at risk of divorce, that is past marriages rather than those of the current year. Divorce rates expressed per 1000 married population are a crude way of achieving this, and rates by marriage cohort or duration of marriage improve on this. A further method is given in the section on synthetic indicators. It is separation rather than divorce that marks the end of informal unions, and measures such as the proportion of cohabitations separating within, e.g., 5 or 10 years are used instead. For many practical purposes, separation is also of greater interest as marking the *de facto* end of a marriage. Information on separation is obtained from retrospective histories of partnership collected in demographic surveys.

Where birth cohort information is available, the cumulative proportions ever having married by specified ages are useful indicators of both the level and the pattern of marriage within and across generations. Birth cohort proportions ever having divorced or ever having remarried can be obtained for the same purpose, though in this case the figures may be influenced by the cohort proportions ever having married or ever having divorced, respectively. The proportion ever having divorced or separated calculated by year of marriage or partnership, specific by duration of marriage/union, overcomes this issue. Similarly, the proportions ever having remarried may be calculated for divorce cohorts, or alternatively the proportions in a new partnership by duration since separation.

Synthetic or Hypothetical Cohort Measures

The total marriage rate is often used to summarize the overall level of marriage for each sex in a population. It is obtained by adding the (type 2) age–sex specific marriage rates and represents the hypothetical average number of marriages in a cohort of women or men if they experienced the age–sex specific marriage rates of a particular year throughout their lifetime. The total first marriage rate is defined similarly as the sum of the age–sex specific (type 2) first marriage rates and represents the proportion of women or men who would eventually marry, if they were subject through their lifetime to the age–sex specific first marriage rates of a given period. Both of these summary measures have the same strengths and weaknesses as the analogous conventional total fertility rate (TFR; *see* Demographic Measurement: General Issues and Measures of Fertility). On the one hand, they are standardized for age and so are an improvement on the crude marriage rate. However, like the conventional TFR they are influenced by timing changes and they do not take account of past history, since they are not standardized for marital status. As a result, a period-specific total first marriage rate can, and has been observed to, exceed one first marriage per person – an impossible result that could not apply in a real cohort. Like the TFR, however, the total marriage rate can be considered as a simple indicator of the level of marriage in a period; like the TFR, it is deficient as a summary indicator whenever change in marriage rates differs between age-groups.

As in the case of fertility, multiplicative summary indicators are available to overcome some of the deficiencies of additive measures: gross nuptiality and net nuptiality. Gross nuptiality is so called because it assumes that all survive to the latest age considered – usually to age 50. It is obtained, for each sex, by combining the age-specific first marriage probabilities of the unmarried (type 1) multiplicatively and computing the proportions ever marrying by 50 years of age (*see* Life Table). Net nuptiality, on the other hand, takes into account that death may intervene before marriage and is obtained by constructing a double-decrement life table, with marriage as one source of decrement and death while single as a second source of decrement (*see* Life Table). Gross nuptiality may be interpreted as the proportion of a cohort who would marry at a given period's age-specific rates if there were no mortality before 50 years of age, and net nuptiality as the proportion who would marry by 50 years of age, at a given period's age-specific marriage and mortality rates. Both gross and net nuptiality require more detailed information than is needed to obtain the total marriage rate – namely first marriages by age and sex together with population estimates by age, sex, and marital status in the case of gross nuptiality, and additionally, mortality rates by sex, age, and marital status in the case of net nuptiality. As with life table quantities in general, they are standardized for age structure.

The level of divorce in a population may also be summarized from period rates using hypothetical cohort indicators. Analogous to the total marriage rate is the male or female total divorce rate, defined as the sum of age–sex specific type 2

divorce rates and representing the average number of divorces per person if the age–sex specific divorce rates of the period in question were to be experienced throughout a person's lifetime. As before, a multiplicative life table-based indicator is preferable to the additive measure. The most common indicator used for the purpose is a life table estimate of the proportions who would divorce by a specified duration of marriage, at current duration-specific rates. As with analogous multiplicative indicators, this not only standardizes for the distribution by marriage duration but also takes some account of past history. It is probably the best available summary measure of the divorce propensity implied by current divorce rates, but is also subject to tempo effects. If successive marriage cohorts are moving to an earlier pattern of divorce, the high divorce rates of early divorcing couples may be combined with the high divorce rates of later-divorcing couples who had lower divorce rates at early durations, to produce an overall hypothetical proportion ever divorcing that is higher than that of any real cohort. Again, the measure can be specified ignoring mortality or incorporating mortality as a competing risk (Wilson and Smallwood, 2008).

Timing

Age at marriage may be calculated from period data in either crude or standardized form, though sources do not always indicate which measure is presented and, as with births, the terms 'crude' and 'standardized' are not in universal use in this context. The crude mean age at marriage is simply the mean age of those marrying in a period. The standardized mean age at marriage is analogous to the standardized mean age at birth and is the mean of the schedule of age-specific marriage rates (type 2). A crude and standardized median age at marriage may also be obtained. It is often useful to distinguish marriage age by the order of the marriage since the proportion of remarriages among all marriages can vary substantially through time or cross-nationally. Thus, we have the mean or median age at first marriage or at remarriage, either crude or standardized. Cohort mean ages at marriage can also be calculated and, as before, do not need to be standardized. Analogous indicators can be obtained for informal unions; the most useful are the mean age at first cohabitation and the mean age at first union. Mean and median ages at marriage can also be obtained from either gross or net nuptiality tables. Care is needed since the e_x column of a nuptiality table does not give the expected age at or years to marriage. Rather the column gives the expected number of years lived while single at and after age x. Since some never marry, this is not the same as the expected number of years to marriage among those who marry (*see* Life Table).

Where direct data are not available, an indirect procedure developed by Hajnal (1953) can be used to estimate the average age at marriage from cross-sectional proportions single (never married) by age. It gives what is termed the singulate mean age at marriage. Based on the hypothetical cohort principle, the procedure is appropriate where marriage rates by age have been reasonably stable and assumes that neither migration nor mortality rates are associated with marital status. Should the proportions single be found to increase over any part of the age range, this indicates that one or more of the assumptions does not hold and so the calculation is not valid. Brief details are given in **Table 1**; see also Preston et al. (2001: Section 4.6).

Mean and median ages at divorce may be calculated. Of particular interest in relation to divorce is the mean/median, etc., duration of marriage at which the divorce occurs. A distinction should be made between the duration of marriages in general – those terminated by either divorce or death – and the duration of those marriages that end in divorce. Crude or standardized versions of these indicators may be obtained; for most purposes, standardized indicators are to be preferred.

Mortality

Table 2 sets out selected mortality measures. These require data on deaths and population estimates. Where such data are not available, indirect methods for estimating mortality are available (*see* Demographic Techniques: Indirect Estimation).

The crude death rate (CDR) – deaths per 1000 population – is widely used as a basic measure of the level of mortality. It is strongly influenced by the age composition of a population because of the wide variation in death rates by age. Age-specific mortality rates – deaths at a particular age per 1000 population of that age – are at the next level of detail, usually specific by sex. Age is usually in 5-year groups and for refined analysis, in single year of age rates. Rates specific by single years of age are of particular importance at the younger and older parts of the age range, since in these age ranges differences in rates between adjacent single years of age may be sizable. Age may be grouped in a variety of ways. However, even where quinary age-groups are used, ages 0 and 1–4 are often distinguished, because of the relatively high death rate of infants, even in low-mortality countries.

The measurement of mortality is simplified somewhat by the fact that death occurs ultimately to all and occurs only once. These two together mean that crude and age-specific death rates are necessarily of type 1 (*see* Demographic Measurement: General Issues and Measures of Fertility). Death rates are so closely and systematically associated with age, and to a lesser extent sex, that specificity by age and sex is adequate for many demographic purposes. Other dimensions of personal time are sometimes used: e.g., duration since diagnosis, or since treatment, in epidemiological studies. Mortality rates may also be specific by social class, race/ethnicity, income, area of residence, marital status, and other socioeconomic characteristics. Analysis by such factors is of interest in examining social and economic variations in health and for actuarial and public health purposes.

The infant mortality rate (IMR) is reported and published extensively, partly as a demographic indicator but also as a proxy for socioeconomic development. It is defined as the number of deaths of infants (children under 1 year of age) per 1000 births in a given year. As the denominator is not an estimate of the person-years at risk of the event, it is, strictly, not a true rate. It has a correctly specified counterpart in the infant death rate, the number of deaths less than 1 year of age per 1000 person-years lived under age 1. The IMR is a convenient measure since it can be obtained from simple counts of vital events and does not require population estimates by age. But it

Crude death rate		
Period; cohort also possible but rare	$\frac{D}{P}$	$D =$ the number of deaths occurring during a particular year/period. $P =$ person-years lived.
Age-specific death rate[d]		
Period; cohort	$M_x = \frac{D_x}{P_x}$	$D_x =$ deaths at age x. $P_x =$ person-years lived at age x or in age-group x.
Infant mortality rate		
Period; cohort	$\frac{D_0}{B}$	$D_0 =$ deaths of infants under 12 months. B = births.
Infant death rate		
Period; cohort	$\frac{D_0}{P_0}$	$P_0 =$ person-years lived aged under 1 year.
Maternal mortality ratio (sometimes referred to as the maternal mortality rate)		
Period; cohort	$\frac{D_m}{B}$	$D_m =$ maternal deaths.
Maternal mortality rate		
Period; cohort	$\frac{D_m}{P^f_{15-49}}$	$P^f_{15-49} =$ woman-years lived at ages $15-49$ (age limits may vary).
Directly standardized death rate[e]		
Period	$\sum_x M^i_x c^s_x$	$M^i_x =$ age-specific death rate in index population i. c^s_x is the proportion of the standard population who are aged x.
Standardized mortality ratio[e] *(SMR)*		
Period	$\mathrm{SMR}^i = \frac{D^i}{\sum_x n^i_x M^s_x}$ or equivalently $\mathrm{SMR}^i = \frac{CDR^i}{\sum_x c^i_x M^s_x}$	$D^i =$ total deaths in index population. $n^i_x =$ numbers aged x in the index population. $M^s_x =$ the age-specific death rate in the standard population. $\mathrm{CDR}^i =$ crude death rate in the index population. $c^i_x =$ proportion who are aged x in index population. The SMR is often multiplied by 100.
Indirectly standardized death rate[e]		
Period	$\mathrm{SMR}^i \times \mathrm{CDR}^s$	CDR^s is the crude death rate in the standard population used in obtaining the SMR.

will approximate less well to the infant death rate when births are appreciably seasonal or that there are sizable year-on-year fluctuations in births. Several mortality rates are distinguished during the first year of life, both because of the steep decline in death rates over the first 12 months of life and because of the changing role of endogenous (genetic, intrauterine, perinatal) and exogenous (environmental, external) causes of death. Endogenous causes predominate in the earliest postpartum period, with exogenous factors growing in importance thereafter. The perinatal mortality rate is defined as the number of late fetal deaths plus the number of deaths within 1 week of birth per 1000 total late fetal deaths plus live births. The neonatal mortality rate is defined as the number of deaths within 1 month (28 days) of birth per 1000 live births, and the postneonatal mortality rate as deaths between 28 days of birth and 1 year of age per 1000 live births. The probability of dying between birth and the fifth birthday is widely referred to in the current demographic literature as the child mortality rate, though the latter is more correctly defined as the number of deaths of children under 5 years of age per 1000 person-years in the age-group. The probability definition (also sometimes termed child mortality risk) has become widespread because under-five mortality is of particular interest in high-mortality, less-developed societies, for which the indirect methods used to evaluate child mortality estimate a cohort probability rather than a rate (*see* Demographic Techniques: Indirect Estimation). High-mortality societies do not usually have good vital registration statistics and it can be difficult to formulate accurate assumptions about the average number of years lived by those who die, and thus to obtain an estimate of person-years lived.

Maternal deaths are those that occur during pregnancy or within 42 days of the end of the pregnancy, due to a cause related to the pregnancy or a condition aggravated by pregnancy, including abortion-related deaths. Maternal mortality

is most often represented by the maternal mortality ratio: the number of maternal deaths per 100 000 live births in a period. This indicator is referred to by many authors and in many sources as the maternal mortality rate, although it is not in fact a true rate. Strictly, the maternal mortality rate is the number of maternal deaths per 100 000 women of reproductive age in a period, and some authors employ the term in this sense. It should be clear from the context which definition is in use. Indirect methods are available to estimate maternal mortality.

Mortality specific by cause of death, of which maternal mortality is an instance, is the principal way in which mortality indicators are disaggregated beyond age and sex. The International Classification of Disease, produced and revised from time to time by the World Health Organization, is the standard scheme by which cause of death is classified. Measures of mortality by cause of death are of two kinds. Cause-specific mortality rates refer to the number of deaths from a particular cause during a period per 100 000 population, and may be specific also by age and/or sex. A multiplier larger than 1000 is normally used for the purpose, since deaths from any one cause will usually be relatively small in number. Cause-specific mortality ratios, on the other hand, relate to the percentage of all deaths that result from a particular cause, either overall or by age and sex, and are of value where information on population denominators is inaccurate or unavailable. Proportional mortality analysis is used particularly in the study of occupational mortality.

Age Standardization

Because of the substantial variation in death rates by age, and in age structure across time and place, cross-national, areal, or time comparisons of the level of mortality require that death rates are standardized for age. The objective is to remove the effect of age structure from the comparison. Direct standardization, in which a standard age distribution is employed, yields a directly standardized death rate. Indirect standardization, based on a standard set of age-specific mortality rates, yields two indicators: the standardized mortality ratio (SMR) and the indirectly standardized death rate. The SMR gives an index figure expressing the level of mortality in the index population relative to that of the standard population, set to 1 or to 100: it is simply the ratio of observed to expected deaths in the index population, with expected deaths based on the standard population's age-specific rates. Multiplying the SMR of the index population by the CDR in the standard population gives the indirectly standardized death rate in the index population. Direct standardization requires that the age-specific mortality rates are known and precisely estimated in the populations to be standardized. Where the age-specific rates are either unknown or subject to sizable errors, the indirect method must be used. Statistical theory singles out a version of indirect standardization as optimal when a multiplicative model holds for the force of mortality.

Life Expectancy and Life Tables

Life expectancy at birth, e_0, is a summary of the overall level of mortality in a population. Because death occurs universally and removes an individual permanently from the population, any increase in death rates at any age is necessarily reflected in a shorter life expectancy, while a decline in death rates at any age is necessarily accompanied by an increase in life expectancy, all else equal. The expectation of life is influenced both by the level of mortality in a population and by the pattern of mortality by age. As a result, two populations with the same overall life expectancy may differ in their patterns of age-specific death rates. Life expectancy is calculated from a life table (*see* Life Table), and so is an age-standardized measure that can be compared fairly between populations and time periods. Life tables are more commonly based on period mortality rates, but are also compiled for birth cohorts. Where based on a period life table, the expectation of life and other life table functions are synthetic cohort measures and do not, strictly, represent the experience of any particular birth cohort. In practice, however, where mortality improvement is gradual, as in developed countries such as the US and Sweden, period life expectancy has been found to approximate to that of the cohort born about 40–50 years before (Goldstein and Wachter, 2006). That mortality change tends to be steady and unidirectional distinguishes it from period fertility, for which an approximate empirical correspondence between lagged synthetic period and ultimate cohort parameters cannot be established. Adjustment of period life expectancy for changing tempo has been proposed and has been subject to much debate (see especially Barbi et al., 2008).

The life table is fairly demanding of data since it requires information on age-specific death rates and hence on both deaths and population estimates by age. Because detailed data of this kind are often unavailable for historical populations and for less-developed nations, sets of empirically based model life tables have been developed corresponding to varying levels and patterns of mortality (Murray et al., n.d.). Such compilations allow estimates of the level and/or age pattern of mortality to be made from information that is insufficient in itself to determine these (*see* Demographic Techniques: Indirect Estimation). For further details of the measurement of mortality see Preston et al. (2001), Rowland (2003), and Siegel (2012).

Migration

Along with births and deaths, migration is the final component of population change. Migration is classified according to whether it is into an area (in-migration) or out of an area (out-migration). The sum of in- and out-migration is termed gross migration and the difference between them, in-migration minus out-migration, is known as net migration. For many purposes it is the absolute values of these quantities that are of interest. Crude and specific rates are also used. The crude in-migration (or immigration) rate is the number of in-migrants per 1000 population and the crude out-migration (or emigration) rate the number of out-migrants per 1000 population. The crude gross migration rate is the sum of these and the crude net migration rate is the difference between them.

There are, however, difficulties with these indicators. In particular, in-migrants are from populations outside the destination area, and a rate of in-migration per 1000

population in the destination area clearly does not link in-migrants with the true population at risk of such migration; it is therefore not a true rate. In addition, net migration is somewhat contested as a category. There is no such thing as a 'net migrant,' and looking for the influences on net migration rather than on the component in-flows and out-flows may be misconceived (Rogers, 1990). On the other hand, it is argued that net migration is useful where information on gross flows is lacking (Smith and Swanson, 1998).

Further indicators based on transition data – having changed residence between specified two time points – are in use. Cumulative migration experience can be represented by whether a person has ever migrated from his or her place of birth or during a specified time, e.g., the last year, the last 5 years. Synthetic summary indicators of lifetime migration experience are also in use, analogous to the fertility equivalent – the gross migraproduction rate, which ignores mortality, and migration expectancy or the net migraproduction rate, which takes mortality into account. Like other demographic events, migration is patterned by age and measures standardized for age can be constructed. For a detailed exposition and discussion of migration measurement, see Bell et al. (2002).

Population Growth

The difference between the crude birth rate (CBR) and CDR is known as the crude rate of natural increase and represents the rate at which a population is growing or declining in a year purely as a result of vital events. Since migration also influences population growth, the overall, crude population growth rate is CBR − CDR ± the crude net migration rate. Where annual crude rates are not available, the population growth rate can be inferred from population size at two time points, say t years apart. If we assume that the population has been growing continuously at a fixed rate over that period, this implies an exponential model of growth, in which $P_t = P_0\, e^{rt}$, where P_0 is the initial population and P_t is population size t years later, and r is the annual growth rate. Under these assumptions, the annual growth rate can be estimated as $r = \ln(P_t/P_0)/t$. Note that the exponential model of growth does not necessarily represent, as is often assumed, extremely rapid growth. Whether exponential growth is rapid depends on the growth rate. For example, after 50 years a population growing exponentially at the rate of 1% per annum would have increased by 65% but the increase would be just 5% if it was growing exponentially at 0.1% per annum.

The growth rate of a stable population – one with a fixed set of age-specific mortality and fertility rates, and closed to migration – is known as the intrinsic rate of natural increase. It is a theoretical quantity. It can be calculated from the fertility and mortality rates of an empirical population. It should be interpreted with care since it is the hypothetical growth rate that would apply in a theoretical stable population with the vital rates assumed, and not the growth rate of the real population from which the vital rates are drawn. Further indicators relevant to the theoretical analysis of population growth are outlined in the article Demographic Measurement: General Issues and Measures of Fertility: the gross and net reproduction rates (GRR and NRR). While the GRR and NRR may be calculated for real populations, the same proviso must be borne in mind: the NRR reflects growth prospects only under strict hypothetical conditions. The same caution is necessary in relation to the TFR: in low-mortality countries, a TFR of 2.1 is widely referred to as 'replacement level fertility,' that is, the level of fertility necessary for population replacement in the long run. But this is potentially misleading. Low-mortality populations with a TFR of below 2.1 can and do continue to grow because of in-migration, declines in mortality, changing fertility, and/or population momentum. Equally, low-mortality populations with a TFR of 2.1 or more can and do decline because of out-migration, changes in fertility and/or mortality, and/or population momentum.

Abstract

Demographic models can have two meanings, one broad and one narrow. In its broad meaning, demographic models refer to all mathematical, statistical, forecast, and microsimulation models that are applied to studies of demographic phenomena. In its narrow meaning, demographic models refer to empirical regularities in age patterns of demographic events. This article is concerned with demographic models in the narrow definition. Demographic models are widely used (1) to improve data quality and (2) to compare demographic outcomes and processes across populations or subpopulations. Both parametric and semiparametric specifications have been proposed for modeling age patterns of demographic events, giving rise to parametric models and semiparametric models. Successful applications of both types of models are found in research on mortality, nuptiality, and fertility. As an integral part of formal demography, demographic models have been linked closely to mathematical demography. In recent decades, however, statistical demography has played an increasingly important role in demographic models.

The term 'demographic models' can have two meanings, one broad and one narrow. In its broad meaning, demographic models refer to all mathematical, statistical, forecast, and microsimulation models that are applied to studies of demographic phenomena. In its narrow meaning, demographic models refer to empirical regularities in age patterns of demographic events. Demographic models in the broad definition can be found in various entries related to demography (*see*, among others, Multistate Transition Models in Demography; Event History Analysis: Applications; Population Dynamics: Theory of Stable Populations; Population Forecasts; Microsimulation in Demographic Research). This article is concerned with demographic models in the narrow definition.

Age Patterns of Demographic Events

In a classic statement, Hauser and Duncan (1959) defined demography as 'the study of the size, territorial distribution, and composition of population, changes therein, and the components of such changes' (p. 2). In the Hauser–Duncan definition of demography, the study of population changes goes hand in hand with the study of the components of population changes. This is necessitated by the need to decompose a population into components and then study changes in the components before arriving at an overall understanding of the changes in the population. The most elementary, and also the most important, form of population decomposition is by sex and age. Since men are only indirectly involved in reproduction, demographic analysis is often simplified by focussing on women. Such simplification is called 'one-sex' modeling (*see* Population Dynamics: Two-Sex Demographic Models), as is commonly seen in fertility and nuptiality models. In mortality models, however, men and women are always kept distinct, and there are substantial mortality differentials in favor of women.

The treatment of age is of significant concern in demographic research. Without exception, the occurrence of all demographic events is age-dependent. Here, the correct interpretation of age-dependency is one of life-course, that is, the likelihood of the occurrence of an event changes as a person (or a cohort) ages. This is true even though most demographic methods and models use cross-sectional data, capitalizing on age-gradients of vital rates in any given population. The use of period-based data usually is necessitated by the lack of cohort-based data.

Demographic models of age schedules are developed on the observation that age patterns of demographic events often show some regularity. Two cautionary notes are in order. First, age regularity is not universal, either across space or over time. Second, all that is assumed is empirical regularity; theoretical reasons behind such regularities are typically neither well established nor well understood. Nonetheless, demographic models capitalizing on empirical regularities are very useful in practice and may provide the basis for theoretical work. A brief discussion of the main uses of demographic models is given as follows.

Use of Demographic Models

Demographic models are intended to summarize empirical regularities in age patterns of demographic events, ideally in simple mathematical formulas. Such models can prove very useful in demographic research. One type of use of demographic models concerns data quality. For example, demographic models may be used to detect and correct faulty data, impute missing data, and allow researchers to infer from partial data. Not surprisingly, this use of demographic models is often found in historical demography and research in less developed countries, where quality data are scarce.

The second type of use is substantive and commonly it is found in research with a comparative focus, be it over time (trends) or across societies, regions, or subpopulations. Age-

schedule models are also useful for actuarial calculations of life-insurance premiums and premium reserves and for the computation of national or regional population forecasts (e.g., Lee and Tuljapurkar, 1994). In demographic applications, cross-group variations in age patterns are typically parameterized as functions of two components: a shape component to capture age effects and a modification component reflecting group membership. Ideally, we would like the second component to be as parsimonious as possible. When demographic models are fully parametric, the two components are integrated, with the functional form being the shape component and the parameter values being the modification component. However, parametric models are not the norm in demography. Parametric models and semiparametric models will be discussed separately below, with concrete examples taken from research on mortality, nuptiality, and fertility. Coale and Trussell (1996) give a more detailed account of some of the models.

Parametric Models

Gompertz (1825) is accredited for the discovery that mortality rates in human populations increase nearly as an exponential function of age. This regularity holds true only after early adulthood (ages 25–30). According to 'Gompertz' law,' the force of mortality (or hazard) is a parsimonious loglinear function of age

$$\mathrm{In}(\mu_x) = A + Bx \qquad [1]$$

where μ_x denotes the force of mortality at age x. Naturally, A is the parameter characterizing the level of mortality at early ages and B is the parameter characterizing the rate of increase in mortality with age. While very parsimonious, the Gompertz model does not always fit empirical data well. Other researchers have modified the model either by adding additional terms or by changing the functional form. For example, Makeham (1867) altered the simple loglinear relationship of eqn. [1] by adding a time invariant term intended to capture cause-specific 'partial forces of mortality.' Heligman and Pollard's (1980) three-component model is another such extension.

In studying age patterns of first marriages among women, Coale (1971) found a basic form that is common in different populations. Through trial-and-error, Coale was able to characterize the typical age pattern of first marriage by a double-exponential curve

$$r_x = (0.174)\exp[-4.411\exp(-0.309x)] \qquad [2]$$

where r_x denotes the hazard rate (or risk) of first marriage at age x. This mathematical function was shown later to be approximated closely by the density function corresponding to the sum of distributions representing demographic processes (Coale and McNeil, 1972).

To fit observed age patterns of fertility, Brass (1960) proposed a model using polynomial functions. Although Brass' parametric model is very flexible, it requires the estimation of four unknown parameters. Since fertility rates typically are given in a limited number of 5-year intervals, this method leaves very few degrees of freedom for evaluating goodness-of-fit. An evaluation of various parametric models based on empirical data is given by Hoem et al. (1981).

There are three notable problems with parametric models. First, parametric models often do not fit observed phenomena. Demographers have dealt with such empirical deviations through (1) restricting the applicable age range and (2) allowing for further parameterization. Both solutions have surfaced in research using the Gompertz model.

The second major disadvantage associated with parametric models is the lack of behavioral interpretations for key parameters. This problem arises from the fact that almost all parametric models have resulted from exercises of curve-fitting. Parametric models may reproduce observed age patterns of demographic events, but theoretical interpretation of involved parameters is often unclear.

Finally, parametric models are not always convenient to use for comparing populations or subpopulations, even though this was one of the motivations for developing them in the first place. This problem is apparent, for example, in the case of a polynomial model. When several parameters in a polynomial function differ between two populations, it is difficult to characterize one population as having higher or lower rates than the other population.

Semiparametric Models

In response to these problems with parametric models, semiparametric models have been developed. Semiparametric models are similar to parametric models in specifying parsimonious mathematical functions but differ from parametric models in allowing age-dependency to be unconstrained and subject to empirical estimation, that is, semiparametric models do not impose any global constraint limiting the age pattern to the rigidity of a parametric mathematical function. Instead, the age pattern is estimated freely and empirically from observed data or calculated from external sources. One manifestation of the semiparametric approach is the use of model schedules or model tables. While allowing for the flexibility in a common age function, model tables place constraints on the variations in the age pattern across populations or subpopulations. Such constraints are often motivated by substantive knowledge of demographic phenomena.

In the area of mortality studies, for example, model life tables have been in wide use, primarily as a tool for correcting faulty data and estimating missing data. In essence, a model life table allows for a typical age schedule of mortality shared by a set of populations that differ mainly in their levels of mortality. The age pattern is flexible and empirically determined over all ages but constrained across populations; and cross-population variability lies in the overall level of mortality. The earliest model life table was developed by the United Nations (1955) for all national populations. Subsequently, Coale and Demeny (1966) added more flexibility by identifying four regional model life tables based on distinctive age patterns of mortality and refined the technique for constructing model life tables.

As an alternative, Brass (1968) developed a system of relational life tables, in which a standard mortality schedule is modified by two parameters through a logit equation

$$\text{logit}(p_{xj}) = \alpha_j + \beta_j \text{logit}(p_x^*) \quad [3]$$

Here p_{xj} is the probability of survival to age x in population j, p_x^* is the probability of survival to age x in a selected standard table, and α_j and β_j are parameters characterizing population j. In the Brass system, α determines the level of survival, whereas β changes the shape of survival parametrically.

In fertility research, Henry (1961) posited the existence of natural fertility with a peculiar age pattern. According to him, for physiological and social factors, different populations not exercising fertility control may have different levels of fertility but exhibit the same age pattern. Coale and Trussell (1974) later formalized this idea into the *Mm* method for studying age patterns of marital fertility. Let the marital fertility rate for the xth age of the jth population be denoted by r_{xj}. The Coale–Trussell *Mm* method parsimoniously describes the cross-population variation in age patterns of marital fertility with

$$r_{xj} = n_x M_j \exp(m_j v_x) \quad [4]$$

Here n_x is the standard age pattern of natural fertility; v_x is a typical age-specific deviation of controlled fertility from natural fertility; and M_j and m_j measure the jth population's fertility level and control, respectively. Equation [4] then states that marital fertility can be modeled as a product of natural fertility and a factor reflecting fertility control. The former is represented by $n_x M_j$; the latter by $\exp(m_j v_x)$. Coale and Trussell estimated n and v and suggested that these age schedules be taken as known in all applications. This approach has been superseded by Xie (1990) and Xie and Pimentel (1992), who suggested that n and v be regarded as parameters to be estimated along with M and m from any set of empirical fertility rates r_{xj}.

Statistical Demography versus Mathematical Demography

The construction and derivation of parametric and semi-parametric demographic model age schedules have been accomplished through mostly mathematical and sometimes graphical methods. From the outset, demographic modeling has been regarded as part of mathematical demography. Since the 1980s, however, a mainline statistical approach has played an increasingly important role in the development of demographic models (e.g., Clogg and Eliason, 1988; Hoem, 1987; Xie, 1990, Xie and Pimentel, 1992) for a number of good reasons.

First, the advancement of demography has brought with it more, richer, and better data in the form of sample data, and the use of sample data requires statistical tools. Treating sample data as exactly known quantities induces the danger of contamination by sampling errors. Second, while the method of disaggregation commonly used in mathematical demography may easily lead to inaccurate estimation due to small group sizes, statistical methods more efficiently utilize covariates to examine group differences. Third, because observed data may sometimes be irregular or simply missing, statistical models can help smooth or impute data. Conversely, the strength of empirical techniques developed around demographic models (e.g., indirect estimation, age patterns of fertility, model life tables, etc.) is that they provide descriptions of age patterns that can be utilized to improve statistical analysis.

Abstract

Demographic data suffer from sampling errors and from biases arising from coverage and content errors that may be systematic and noncompensating. Common and problematic errors for demographic estimation are those affecting the reporting of age, parity, and deaths. Age misreporting affects population counts and vital rates. Techniques of data evaluation and correction relying on individual-level analysis include the postenumeration survey, imputation, capture–recapture methods, and statistical analysis. Techniques using aggregate-level data employ digit preference indices, sex and age ratios, and smoothing; demographic accounting and internal consistency; and parametric functions, relational models, statistical modeling, and time-based methods.

Demographic data suffer from sampling errors and from nonsampling errors related to coverage and content. Nonsampling errors are often systematic and noncompensating, introducing biases in the same direction rather than random. Such errors are more common or more serious in populations with lower levels of education and economic development. Errors in the reporting and classification of age, parity (number of live-born children), and deaths are the most common and most problematic for demographic measurement and estimation. Techniques of data evaluation and correction may rely on re-enumeration and matching of individual records, data editing, and individual-level statistical analysis and modeling. Alternatively, analytical methods based on population-level aggregated data may be applied, using mathematical formulae, statistical modeling, and the relationship between demographic processes (birth, death, and migration) and age distribution.

Types of Errors

Sampling Errors

Issues such as sampling errors, sample size, and representativity apply to data collected through sample surveys. This increasingly includes data traditionally collected through the census, because many countries (e.g., USA, France, China) are turning to sampling techniques to avoid the cost of complete coverage.

One of the critical factors in determining sampling error is the sample size: the larger the sample, the smaller the sampling error. But the overall size of the population surveyed, cost, and logistical issues often limit the sample size. In a simple random sample, doubling of the sample size will decrease sampling error by 30%. To double the accuracy requires quadrupling the sample size, incurring associated costs. Stratification and more complex sample designs can also help to improve the accuracy of the results (ICF International, 2012b; United Nations, 2005; United Nations, 2008a).

Sampling errors need to be accounted for when analyzing the data. Differences in means or proportions between subgroups, for instance, should always take into account standard errors to determine whether differences are statistically significant within a margin of error. The increasing availability of statistical software able to handle complex sample designs makes it easier to undertake analyses that appropriately take standard errors into account (Deaton, 1997).

The overall size of the population under study is also relevant for the computation of standard errors of vital rates by age (and sex). Random fluctuations in events in small populations (often due to disaggregation by particular characteristics or by small areas) can be addressed by pooling multiple years to ensure a sufficient number of person-years of observation. This is often necessary when computing life tables for small areas or subpopulations (Eayres and Williams, 2004; Scherbov and Ediev, 2011; *see* Life Table; Demographic Techniques: Small Area Estimates and Projections). Pooling of data is also useful for sample data when sample sizes are small (Dwyer-Lindgren et al., 2013; Pedersen and Liu, 2012).

More general issues related to sampling theory and sample design, such as the computation of sampling errors and design effects, are beyond the scope of this section and are addressed in sampling statistics textbooks (Kish, 1965; Levy and Lemeshow, 2013; Lohr, 2009; Som, 1996).

Errors of Coverage

Coverage errors are nonsampling errors and result in bias, affecting the representativity of the data. Coverage errors may occur in data collected through both censuses and sample surveys.

In censuses, errors of coverage comprise the underenumeration or (less commonly) the overenumeration of individuals in the population. Underenumeration occurs when areas, settlements, or households are erroneously omitted from the census, and when individuals within (otherwise covered) households are not enumerated. Outdated or incomplete maps or housing listings, a shortage of trained and experienced interviewers, inadequate field supervision, extreme remoteness or inaccessibility, political or security problems, conflict zones,

difficulties in locating nomadic people and those living in slums or refugee camps, refusals to be enumerated, and loss of census records after enumeration may all contribute to the underenumeration of households. Short-term migrants and infants are among household members most likely to be omitted from enumeration. Overenumeration may arise from double counting, which can occur as a result of poor planning and management of fieldwork leading different interviewers to enumerate the same household or as a result of migrants and more mobile persons (e.g., household members who are temporarily absent, traveling, studying or working elsewhere) being reported both at their household and at their place of visit, work, or study (United Nations, 2008b). Overenumeration also occurs when ineligible persons (e.g., visitors or nonresident aliens) are enumerated as if eligible. Sex-selective underreporting of girls, especially when reporting is by proxy, may also occur in settings favoring sons (e.g., parts of South Asia), especially in the context of restrictive child policy (e.g., China).

Surveys are affected by similar problems. Sample underrepresentation of the population may arise from use of an outdated or inadequate sampling frame for the selection of primary sampling units (usually households), particularly in countries lacking a census in the past decade or where population change has been rapid. Similar sampling bias occurs when a sampling frame systematically excludes some population members (e.g., when a reproductive health survey samples only family housing units, thereby excluding women living in institutions or collectives) or where the probability of selection is lower for certain population members (e.g., because of cultural differences in defining who is a household member (Randall et al., 2013, 2011)). In reproductive health surveys, these issues can lead to single women being omitted (Hull and Hartanto, 2009), or to the overrepresentation of women with more children (Avery et al., 2013), upwardly biasing fertility. The extent of the resulting bias will depend on the difference in the variable of interest between those omitted from and included in the sample, and on their fractions of the total population.

Moreover, the representativity of the sample can be compromised by selection biases during fieldwork (United Nations, 2008a). For example, interviewers may predominantly visit households that are easier to reach (along main roads, for instance) especially in conflict zones (Johnson et al., 2008), or they may miss households that have been recently dissolved due to mortality or selective out-migration of the population at risk in zones experiencing conflicts or crises (Walker et al., 2012), leading to biased mortality estimates, *see* Selection Bias, Statistics of. In addition, many surveys restrict some questions to subgroups of individuals based on eligibility criteria such as sex and age (e.g., females aged 15–49 for questions on reproduction) or duration (e.g., vital events in the last 5 years). Interviewers often need to assess eligibility when respondents either do not know (even after probing) or when values are close to the eligibility limits (ICF International, 2012a), because of the implications in terms of extra workload (i.e., additional sets of questions to collect on supplementary topics). The interpretation by interviewers of selection filters can lead to the omission of potential respondents or events and to shifting of dates or ages (ICF Macro 2009; Pullum, 2006; Silva, 2012; Sullivan, 2008).

Incomplete coverage is also a common deficiency of vital registration data. Further, since year of registration rather than year of event is the usual basis of compilation, late reporting adds to the inaccuracies involved. Births are more affected by late reporting because registration is often not required until children reach school age. Death registration, where it occurs, is usually fairly timely since registration is often a legal requirement for burial; though in some populations such requirements are often ignored, notably in rural areas, leading to underregistration rather than late registration.

Nonresponse is a further source of bias and nonrepresentativity (Groves and Couper, 1998). Item nonresponse occurs when only partial information is collected for an individual. For most variables, nonresponses are omitted from analysis, only their extent being reported; this implicitly assumes that respondents and nonrespondents do not differ with respect to the item in question. For age, nonresponses are often distributed on a *pro rata* basis for each sex because of the need to maintain population size in demographic measurement; this also assumes no difference in the age distributions of respondents and nonrespondents. These assumptions may be erroneous and care is needed in the interpretation of results, especially if nonresponse is substantial.

Errors of Content

Misclassification and content error may affect all demographic variables. These errors arise from incorrect substantive reporting on the part of the respondent and/or interviewer, or from mistakes during data processing. Some errors may be caused by specification error, including poorly phrased questions or instructions, ambiguity of interpretation, and respondent misunderstanding or inability to distinguish key concepts, for example, respondent's biological children from children of brothers or sisters living in the same household. Other errors may be related to the mode of data collection (e.g., length and place of interview, order of questions, whether through interview or self-administered questionnaire, etc.) and interviewer effects (e.g., interviewer errors in phrasing questions or transcribing responses). Errors on the part of the respondent may include digit preference, telescoping and memory lapse related to long recall periods, deliberate misreporting, and errors due to proxy responses. Finally, data processing errors may occur during coding, data entry, editing, analysis, or dissemination (United Nations, 1982; United Nations, 2005).

Assessment and Adjustment of Individual-Level Data

The evaluation and adjustment of individual-level data may be achieved through the use of postenumeration checks, data editing, and individual-level statistical analysis and modeling.

Both coverage and content of surveys and, in particular, censuses are assessed through the postenumeration survey

(PES). The PES involves the recollection of data for a representative selection of the original population or sample. The two sets of data are matched for each individual enumerated in the PES (Alho and Spencer, 2006; United Nations, 2010b; United States. Bureau of the Census. 1985). Similarly, event capture–recapture and matching methods, using two or more independent data sources for a representative sample of cases, are used to estimate the completeness of birth and death registration or of retrospective reports from censuses or surveys (Amstrup et al., 2005; Krótki, 1978; United Nations, 1991). This general approach is regarded as the gold standard, but its cost and complexity often limit its usage. Dual-registration systems (e.g., India's sample registration system (Mahapatra, 2010) and China's disease surveillance point system (Yang et al., 2005)) rely on this approach to derive adjusted sample vital statistics using the Chandrasekaran–Deming formula (1949).

Methods employed to address coverage issues due to unit nonresponse include the use of longitudinal data. Survival analysis and other longitudinal methods such as random- and fixed-effects modeling can deal with issues such as loss to follow-up and censoring (*see* Survival Analysis: Whether, and If So, When?; Panel Surveys: Uses and Applications). In addition, even with cross-sectional data, various multivariate statistical methods can be used to correct for sample selection biases (Stolzenberg and Relles, 1997; Winship and Mare, 1992).

Item nonresponses affecting content can be addressed during data editing or analysis. Missing responses, for instance, may be imputed based on responses from other respondents with similar known characteristics (United Nations, 2010a). In recent years, the greater availability of microdata sets and more advanced multivariate statistical software have made it increasingly easy to apply multiple imputations based on extensive sets of household or individual characteristics (Little and Rubin, 2002; Schafer, 1997), thus allowing missing values to represent multiple sets of plausible values and to analyze data without assuming that nonresponses are missing at random (*see* Multiple Imputation).

Content errors such as digit preference can also be analyzed at the individual level through the use of multinomial logistic regression. An example is Pullum's (2005, 2006) adaptation of the Myers' blended method (Hobbs, 2004; see also below section Evaluation and Adjustment of Population Distribution by Age) for the estimation of interpretable misreporting parameters based on covariates (with standard errors and confidence intervals corrected for sample design). In addition, general patterns of digit preference can be modeled statistically, and the age distribution can potentially be adjusted without imposing any other constraint than a smoothness assumption for the underlying true distribution. For example, Impicciatore and Billari (2011) proposed a general method to estimate smoothed age profiles and relative risks for time-fixed and time-varying covariates using generalized additive models; and Camarda et al. (2008) proposed a method to estimate the unobserved latent distribution, free of the effects of misreporting, using a composite link model with a penalized likelihood.

Until recently, the evaluation of individual-level data had been the prerogative of national statistical offices or other agencies charged with data collection and custody. The increasing access to microdata enables a wider range of users to directly apply and develop methods of evaluation and correction, greatly improving capability in this area.

Assessment and Adjustment of Aggregate-Level Data

Many analytical methods of assessment and adjustment are based on aggregated data. These methods use mathematical formulae, statistical modeling, and the relationship between demographic processes (birth, death, and migration) and the age distribution.

Assessment and Adjustment for Completeness

The completeness of a census enumeration may be assessed, at the aggregate level, through analytical demographic methods using successive censuses and intercensal estimates of the components of population change (Alho and Spencer, 2006; United Nations, 2010b; United States Bureau of the Census, 1985). Similarly, the completeness of birth and death registration (or of retrospective reporting in censuses and surveys) may be assessed at the population level using demographic relationships (*see* Demographic Techniques: Indirect Estimation). For example, vital rates can be compared across independent data sources for similar periods or cohorts, and analyzed for consistency in age-specific trends in rates and sex ratios; such analyses may also be disaggregated by the characteristics of the deceased or, in the case of fertility, of the mother, or of the household (United Nations, 1991). Adjustment factors are usually based on the reciprocal of the estimate of the completeness of vital registration for the total or disaggregated population.

In addition to these approaches, the completeness of adult death registration (or reporting in censuses or surveys) can be evaluated using death distribution or growth-balance methods. These methods require the availability of death data and at least one census, and preferably two or more censuses (Hill et al., 2009; Moultrie et al., 2013; United Nations, 2002). Death distribution methods assume that age is accurately reported, and therefore do not correct for age misreporting, which at older ages usually involves exaggeration in age at death leading to downwardly biased mortality rates (prior to the open-ended age group). These methods address only relative under- and overreporting of registered age-specific deaths against intercensal estimates, which are potentially biased by differential accuracy of census enumeration, and by migration in the intercensal period (Bhat, 2002). In addition, they assume that both the proportion of deaths registered and the completeness of the census enumerations are constant over adult ages. More robust results are usually obtained by combining the results of growth-balance methods and synthetic extinct generations methods (Hill et al., 2009), and using various age combinations (e.g., 20+/50+, 5+/50+, 5+/65+) to minimize the perturbating effects of violations of underlying assumptions in each method (Murray et al., 2010). The resulting estimates of completeness are used to adjust registered deaths.

These estimates of mortality and others obtained from indirect methods (e.g., intercensal cohort survival,

orphanhood, siblings, widowhood – *see* Demographic Techniques: Indirect Estimation) can be compared across methods using different data sources. The most reliable and robust estimates can be used as a baseline reference to potentially adjust more deficient data sources (Hill et al., 2005; Moultrie et al., 2013; Timaeus, 1991; United Nations, 2002).

Evaluation and Correction of Parity Data

Parity data, or number of live-born children a woman has borne, are collected through censuses and surveys or at birth registration. Errors in the reporting of parity often involve understatement due to the omission of births, especially births of girls. Analysis of sex ratios of births by parity (of women) can reveal systematic sex-selective understatement due to gender preference (*see* Missing Girls: A Globalizing Issue). Where adoption is common, overstatement may occur due to both the natural and adoptive mother reporting the birth (Moultrie, 2013a). The inclusion of stillbirths as live births also results in slight parity overstatement.

Omissions of births may be detected and corrected by indirect estimation (*see* Demographic Techniques: Indirect Estimation). Further error arises when childless women are recorded as 'parity not stated' due to the ambiguous use of the dash symbol (–) by interviewers. If these apparent not-stated cases are excluded, average parity is overestimated. If all not-stated cases are included and treated as childless, average parity is underestimated. The El-Badry correction estimates the proportion of women with parity not stated, who are in fact childless (El-Badry, 1961; Moultrie, 2013b). Based on the observed high correlation between true proportions of childless, $Z^*(i)$, and proportions of parity not stated, $NS(i)$ where $i = 1$ to 8 represents the age groups 10–14 to 45–49, El-Badry assumes $NS(i) = \alpha\ Z^*(i) + \beta$, where α is the proportion of truly childless women who are erroneously recorded with parity not stated and β is the constant true proportion of parity not stated. Since the reported proportions of childless, $Z(i)$, equal $(1 - \alpha)\ Z^*(i)$, then $NS(i) = [\alpha/(1 - \alpha)]Z(i) + \beta$, and $\alpha/(1 - \alpha)$ and β can be estimated by ordinary least squares based on the first four or five age groups. Then, β is used to estimate the number of women in each age group for analytical purposes, and true proportions childless are estimated by $Z^*(i) = Z(i) + NS(i) - \beta$. This correction is based on all women. If data on parity are available only for ever-married women (in which case all never-married women are generally assumed childless), the procedure can be applied on the assumption of a linear relation between the proportions of ever-married women who are childless and who have parity not stated.

Evaluation and Adjustment of Population Distribution by Age

Errors in the reporting of age can affect population counts and vital events. Age misreporting includes digit preference (or age heaping) and age under- and overstatement, which may occur together. Digit preference occurs when real age is not known and its estimation involves the 'rounding' of age (or year of birth) to end in a preferred digit such as 0 or 5. Digit preference is best detected graphically. **Figure 1**, for example, shows persistent age heaping across the last five censuses of India.

Various indices have been devised to measure the extent of digit preference in population counts, but they do not offer a means of correction (Hobbs, 2004). Whipple's index measures the preference or avoidance of the digits 0 and 5 over

the age interval 23–62, though other multidecennial intervals can be used. Myers' blended index measures preference or avoidance of all 10 digits. Since neither index is theoretically precise, Bachi derived a composite index without this deficiency. Whipple's and Myers' indices assume rectangularity or linearity within quinquennial age groups. Later indices, developed by Carrier and by Ramachandran, take account of age structure and variable digit preference over the age range. In practice, the Bachi, Carrier, and Ramachandran indices are laborious and are used less frequently. Given the focus of Whipple's index on 0 and 5, its value in reflecting improvements in the quality of age reporting diminish as digit preference becomes less common (Spoorenberg, 2009). The Myers' blended index and the total modified Whipple's index provide better assessments of the overall spatial and temporal variability of age reporting (Spoorenberg, 2007).

Age misstatement generally involves a directional tendency often related to cultural factors (Ewbank, 1981; Pullum, 2006). Age understatement may occur among women of lower parity than average for their age, especially in cultures with high fertility. Age overstatement often occurs at older ages, particularly among males, in cultures where status is gained with age. Other sex-specific age misstatement may also occur. For example, young female children generally are reported as younger than their male peers. Inaccuracies in the reporting of age tend to be more accentuated in vital events than in population counts. In the case of deaths, age exaggeration may partly be related to proxy reporting. Overstatement in age at death can lead to substantial underestimation of mortality at older ages (Coale and Li, 1991; Condran et al., 1991; Preston et al., 1999) and even to abnormal crossovers and paradoxes between population subgroups when such errors affect more systematically some subgroups than others (Elo and Preston, 1997; Elo et al., 2004; Preston et al., 1996; *see* Mortality Crossover).

In many cases, it is impossible to distinguish between age misstatement, differential coverage by age, and digit preference. Further, one error may offset another. For population counts, the pattern of overall error may be seen by examination of age ratios and sex ratios for 5- or 10-year age groups (Hobbs, 2004; Pullum, 2006). **Figure 2** illustrates these deviations for the 1991 census of India. Panel A shows the age distributions by sex. Panel B shows how sex ratios by age differ from sex equality (sex ratio = 100), indicating distortion due to age misreporting (given sex differences in migration and mortality). Panel C shows age ratios by sex, contrasting over- and understatement of age by age group. These sex and age ratios may also be compared with ratios from suitable model life table populations or smoothed age distributions (as seen in **Figure 2**).

An indication of the overall accuracy of age reporting is given by the United Nations age-sex accuracy index (or 'joint score') (United Nations, 1955). This index assumes no significant irregularities by age (i.e., limited change in past birth cohort size) and sex parity at all ages (implying equal numbers of male and female births and equal mortality). Since the index assumes that all irregularities are errors, it should be interpreted with caution in populations affected by historical events (e.g., baby booms or baby busts, age–sex-specific migration, or mortality shocks or crises).

Errors may also be assessed through comparison with expected counts and distributions based on external data using demographic relationships (Pollard et al., 1990; Preston et al., 2001b). When accuracy permits, a previous enumeration of a population can be 'updated' using data on births, deaths, and net migration to derive an expected age distribution using a cohort-component population projection (Himes and Clogg, 1992; United States Bureau of the Census. 1985). Consistency between the enumerated population at older ages (e.g., age 80 and over) and recorded deaths can be enforced by using the (almost) extinct generation method when death registration records are considered more reliable than census information (Andreev, 2004; Machemedze and Dorrington, 2011; Wilmoth et al., 2007). Comparison of the cumulative age distribution with model stable distributions may identify distortions due to misreporting, in the absence of substantial migration and assuming no significant changes in past fertility and mortality. A suitable model stable population can also be used to derive the structure of the open-ended age group when it is unknown (United Nations, 1983; *see* Population Dynamics: Theory of Stable Populations). When fertility and mortality have been declining in recent decades (as in many countries), the availability of two or more censuses can help to assess the accuracy of age distributions by examining cohort consistency between censuses, and by allowing the assumption of stability to be relaxed by iteratively fitting projected population structures to the observed numbers (Bhat, 1990). Using successive censuses, cohorts can be compared at different points in time: allowing for mortality, the (smoothed) age distributions enable the detection of possible enumeration inconsistencies. **Figure 3** shows the detection of missing infants and young adults in the 1991 census of India.

The effects in demographic measurement and estimation of both digit preference and age misstatement can be reduced by collecting exact date (or at least year) of event rather than age and by using wider (than standard 5-year) age intervals at the analysis stage, though this is not always practicable and involves greater approximation. Similarly, the effects on standard quinquennial age groups can be reduced by adopting nonstandard age groups, the optimum choice of which is based on Myers' index (Hobbs, 2004), but these are generally inconvenient for analytical and comparative purposes.

For many purposes it may be appropriate to smooth or graduate the age distribution. Methods of smoothing include the use of graphs (manual smoothing), moving averages, curve fitting, and statistical modeling. Mathematical graduation is used to smooth narrower age groups within broader age groups. The Carrier–Farrag and Karup–King–Newton formulae treat all age groups the same, whereas the Arriaga's formulae treat the first and last differently (Arriaga et al., 1994). In the following formulae, ${}_nP_x$ represents the population aged x to $x + n - 1$, x and n being integers. The Carrier–Farrag ratio method defines the relationship of a 5-year age group to the 10-year age group of which it is a constituent as

$$ {}_5P_{x+5} = {}_{10}P_x \Big/ \left[1 + \left({}_{10}P_{x-10} / {}_{10}P_{x+10}\right)^{1/4}\right] \quad \text{and} $$
$$ {}_5P_x = {}_{10}P_x - {}_5P_{x+5} $$

The Karup–King–Newton formula assumes a quadratic relationship between three consecutive 10-year age groups, that is, ${}_5P_x = \frac{{}_{10}P_x}{2} + \frac{\left({}_{10}P_{x-10} - {}_{10}P_{x+10}\right)}{16}$. The Arriaga's formulae are based on second-degree polynomials passing through the midpoints of three consecutive 10-year age groups. Then

$$ {}_5P_{x+5} = \frac{\left(8\,{}_{10}P_x + 5\,{}_{10}P_{x+10} - {}_{10}P_{x+20}\right)}{24} $$

when the 10-year age group is the first,

$$ {}_5P_x = \frac{\left(-\,{}_{10}P_{x-20} + 5\,{}_{10}P_{x-10} + 8\,{}_{10}P_x\right)}{24} $$

when it is the last, and

$$ {}_5P_{x+5} = \frac{\left(-\,{}_{10}P_{x-10} + 11\,{}_{10}P_x + 2\,{}_{10}P_{x+10}\right)}{24} \quad \text{otherwise} $$

In all cases, the second 5-year age group is derived by subtraction with ${}_5P_x = {}_{10}P_x - {}_5P_{x+5}$

When age misreporting is more severe, the totals of all age groups need potential modification. The United Nations formula lightly smooths 5-year age groups, based on five consecutive 5-year groups, and gives the smoothed population aged x to $x + 4$ as

$$ {}_5P'_x = \frac{\left(-\,{}_5P_{x-10} + 4\,{}_5P_{x-5} + 10\,{}_5P_x + 4\,{}_5P_{x+5} - {}_5P_{x+10}\right)}{16} $$

For heavier smoothing, three consecutive 10-year age groups are used to derive the central smoothed age group as

$$ {}_{10}P'_x = \frac{\left({}_{10}P_{x-10} + 2\,{}_{10}P_x + {}_{10}P_{x+10}\right)}{4} $$

Neither formula smooths the youngest and oldest age groups. Since smoothing changes overall population size, the smoothed age groups are adjusted proportionately to achieve

Figure 4 Analysis of the distribution by single age and sex of the 1991 census of India. Reported data by age and sex (solid gray bars) show digit preference. the enumerated total. The Arriaga's (or other such) formulae are then applied to smoothed and adjusted 10-year age groups to derive smoothed 5-year age groups. An example of heavier smoothing is seen in Figure 2.

A single-year age distribution may be derived from grouped data by adopting the within-group distribution of a suitable unabridged life table population, but discontinuities at age-group junctions are inherent in this approach. A smoother distribution is obtained by mathematical interpolation, such as osculatory interpolation, which is especially useful for irregular data because of the constraint of continuity at junctions. Sprague multipliers employ fourth- and fifth-difference osculatory interpolation to smooth single-year data within 5-year age groups without changing the totals. They are less satisfactory for the first and last two age groups and where there is marked curvature (see Figure 4). Sprague multipliers can be employed with any continuous data including rates, for any age partition (e.g., tenths), and with unequal age intervals. A blended distribution can be derived by averaging smoothed distributions obtained by osculatory interpolation within the five possible age groupings with terminal digits 0–4, 1–5, 2–6, 3–7, 4–8 (Figure 4).

Spline interpolation is a more sophisticated type of osculatory interpolation that has become more widely used with increasing computing power. Spline interpolation involves extensive iteration resulting in a highly smoothed distribution (Judson and Popoff, 2004). The approach is very flexible, can be used on counts, proportions, rates, and ratios, and is applicable to any age groupings including those of unequal length. Monotonicity can be imposed using penalized splines (Ligges, 2013; Schmertmann, 2012; Smith et al., 2004); and weighted splines allow for unequal variance by age (Booth et al., 2014). More robust results may be obtained by application to cumulative distributions, with differencing of the interpolated results (Wilmoth et al., 2007).

Adjustment of Age Patterns in Demographic Processes

In addition to spline interpolation of rates by age (Section Evaluation and Adjustment of Population Distribution by

Age), specific analytical methods are available for the smoothing and adjustment of rates or age distributions. These methods include relational models and predefined mathematical functional forms.

Relational models are used when the data suffer from biases due to reporting error. An empirical standard or reference distribution is used to adjust the data. The observed distribution is related to the standard through a two-parameter linear model after applying a suitable transformation (e.g., Logit) to both distributions. Thus, the adjusted distribution is the best-fitting (over the age range employed) linear function of the standard.

For mortality, the Brass Logit life-table system involves fitting observed data to a standard model life table (Brass et al., 1968; *see* Demographic Models; Stochastic Models; Population Forecasts). A larger number of parameters help to address mortality deviations from the standard at young and old ages (Ewbank et al., 1983; Rachet et al., 2008; Zaba, 1979). For fertility, the Brass Relational Gompertz model is used with an appropriate standard, such as the Booth Standard for high fertility (Booth, 1984; Brass, 1974; Moultrie, 2013c; *see* Demographic Models). The adjustment of immigration and emigration data can also be achieved through relational models (Zaba, 1985).

Relational models are flexible and easy to apply, but the adjusted distribution is influenced by the choice of the reference standard (Moultrie, 2013d). Ideally, a more context-specific standard is used (De Beer, 2012; INDEPTH Network. 2004; Murray et al., 2003; Wang et al., 2012; Wilmoth et al., 2011). To reduce dependence on the chosen standard, the relationship between observed and standard fertility or mortality may be modeled by splines (De Beer, 2011, 2012).

Mathematical functions are used in demographic modeling and data smoothing. A parametric function is fitted to the empirical observations, imposing a functional form on the data. This approach is advantageous when data availability is limited to certain ages, or when the data are too noisy for nonparametric smoothing to provide a plausible functional form. Adult mortality rates, especially at older ages, are often smoothed and potentially adjusted using the Gompertz or Makeham functions (Heuveline and Clark, 2011), typically fitted to adult mortality rates and used to smooth and extrapolate mortality at older ages. For observed mortality at the oldest ages (e.g., 85 and over), additional smoothing or adjustment may be achieved using the Kannisto model of old-age mortality (Thatcher et al., 1998) fitted to data at age 75 and over. Adjustments to old-age mortality ensure consistency (Condran et al., 1991) by age (e.g., monotonic increase), over time (e.g., monotonic decline) and between the sexes (e.g., male rates greater than or equal to female rates). Where mortality rates must be smoothed and adjusted at all ages, additional terms are required to model infancy and childhood, and young adulthood. Several parametric functions serve to model the whole age pattern of mortality (e.g., Heligman and Pollard (1980), Kostaki (1992), Siler (1983), Carriere (1992); see reviews by Gage and Mode (1993) and Booth and Tickle (2008)).

Parametric functions are also used to model the age patterns of nuptiality and fertility (Preston et al., 2001c); see review by Booth (2006). The Coale–McNeil (Coale and McNeil, 1972) parameterization of nuptiality applies to first marriage (Coale, 1971; Hernes, 1972) and can be used to model first births (Bloom and Trussell, 1984). The parsimony of these models and the functional shape they impose on the data are useful to smooth and adjust poor-quality data. However, their ability to appropriately model empirical observations depends on their flexibility to capture the range of situations experienced by various countries over time (e.g., the emergence of bimodal fertility distributions by age in low fertility populations (Bermúdez et al., 2012)).

Migration is modeled by the multiexponential function (Rogers and Little, 1994), which is useful in imposing a smooth age pattern on data that are often highly defective; see also Booth (2006). Rogers et al. (2010) demonstrate how to combine smoothing to remove randomness with the use of the multiexponential and empirical schedules to adjust immigration and emigration data.

Adjustments over Time

Demographic series for two or more points in time can be used to evaluate trends, growth, and structural population change. Time series facilitate interpolation and extrapolation. In particular, time series of population counts and the demographic processes of birth, death, and migration jointly enable the derivation of robust estimates.

One of the most common adjustments in demography is shifting the population to refer to a specific date, such as 30 June. This may be achieved in two ways: first by linear or exponential interpolation of each age group between two time points (Arriaga et al., 1994); and second by adjusting the total population exponentially (the growth rate is required) and assuming the same age–sex structure as at the nearest enumeration. This last option is valid only for shifts of short duration (i.e., a few years). For longer extrapolations, a cohort-component population projection with assumptions about fertility, mortality, and migration trends should be used.

Age-specific growth rates can also be employed to assess and potentially adjust age-specific data through demographic relationships in nonstable populations using the variable-r approach (Cai, 2008; Preston and Coale, 1982; Preston et al., 2001a; Schmertmann, 2002; *see* Population Dynamics: Theory of Nonstable Populations). This approach, which may also use duration-specific data, assumes no significant changes in patterns of age misreporting and completeness of coverage between enumerations.

When demographic events in a reference time period are reported retrospectively, errors of timing may occur (e.g., displacement and recall lapse). For births, such errors are often corrected through indirect estimation (*see* Demographic Techniques: Indirect Estimation). Consistency between successive censuses and surveys for overlapping periods can be analyzed visually, as well as through robust statistical modeling of time trends (Pullum, 2006). Inconsistencies can be resolved by the adjustment of indices over age or over time using splines (or locally weighted regressions), with the optional use of covariates and hierarchical statistical modeling to take account of likely biases associated with factors such as method of data collection or length of recall period (Alkema and New, 2013; Alkema et al., 2012). The

increased availability of both microdata and internationally comparable public use data sets have made it increasingly possible to perform pooled analyses of multiple datasets for a country, and to analyze all countries simultaneously to detect potential systematic biases and to adjust them if possible. Such statistical modeling approaches are being increasingly used to derive robust time series estimates (with uncertainty bounds), including for child mortality (Alkema and New, 2013; Hill et al., 1999), maternal mortality (Lozano et al., 2011; Wilmoth et al., 2012), adult mortality (Masquelier et al., 2013; Obermeyer et al., 2010; Wang et al., 2012), fertility (Alkema et al., 2012; Machiyama, 2010; Schoumaker, 2011, 2013), and contraception (Alkema et al., 2013). Furthermore, simultaneous estimation of population counts and vital rates (taking into account the underlying uncertainty in each data source) can be used to ensure internal consistency between all demographic components (Luther et al., 1987; Luther and Retherford, 1988; Wheldon et al., 2013a, 2013b; 2013c).

Abstract

Family reconstitution is the technique of linking records of demographic events, usually of an ecclesiastical nature (baptisms, marriages, burials), within and between individual lives to recreate individual life histories and the histories of families. Methods of family reconstitution include purely manual linkage, computer-assisted manual linkage, and linkage solely by computer. Family reconstitution has given scholarship a remarkable window on the demographic past. In so doing it provides information for much longer spans of time than contemporary data and often for periods before any effects of industrialization or modernization.

Family reconstitution is the technique of linking records of demographic events, usually of an ecclesiastical nature (baptisms, marriages, burials), within and between individual lives to recreate individual life histories and the histories of families. It originated with studies that linked by name the originally separate parish records of baptisms, burials, and marriages (*nominal data linkage*) of family members. It revolutionized the study of population processes in the past, allowing estimation of demographic rates that were virtually impossible to obtain by other means. Extensions of the technique have been applied to related sources such as genealogies, *Ortssippenbücher* (local books of family histories), civil vital event registers, civil population registers, *Libri status animarum* (*Book of the State of Souls*), and *censuses*. Methods of family reconstitution include purely manual linkage, computer-assisted manual linkage, and linkage solely by computer. Some limitations of the technique include data quality, coverage, and representativeness; statistical issues; selection by quality of data; selection by migration, truncation, and censoring; and bias from delays in recording. Despite difficulties in quality and coverage of the data and the possibility of biased inference, family reconstitution has given scholarship a remarkable window on the demographic past. In so doing it provides information for much longer spans of time than contemporary data and often for periods before any effects of industrialization or modernization.

The Technique

Family reconstitution is the technique of linking records of demographic events within and between individual lives, in order to recreate individual life histories and the histories of families. Early studies largely made use of ecclesiastical records, but recent studies make use of a wider variety of data. While genealogists have always pursued such linking, the intent of demographers is not simply to record chains of descent and marriage but rather to compile information on the *demographic rates* pertaining to the *population* of which the individuals and families were a part.

Family reconstitution has allowed estimation of demographic rates in populations for which population statistics were not available. Demographers ordinarily estimate vital rates by comparing counts of events in vital records to counts of the population at risk in a census. For example, the crude birth rate is estimated by dividing the number of births in a year by the total size of the population. However, accurate censuses contemporary with records of vital events are rare in the past. Family reconstitution overcomes this difficulty by counting both events and persons. Application of family reconstitution has led to important insights. For example, it showed (in contrast to the expectations of Notesteinian theory) that the decline of fertility in some places occurred well before economic modernization and before any decline in mortality.

History and Scope of the Technique

Family reconstitution as a demographic technique was developed initially by Swedish demographers (Edin, 1915) and advanced by the French (Henry, 1967), then by English scholars (Wrigley, 1966; Wrigley et al., 1997). It linked by *names of persons* the parish records of baptisms, burials, and marriages of individuals (hence the technical phrase, *nominal data linkage*). Genealogists had always used the linking of disparate records by names of individuals. Its large-scale use by historical demographers was an innovation. Nominal data linkage is of course now commonplace, especially using unique identifiers, in the management of medical, insurance, taxation, police, and other data, especially by computer. In the hands of historical demographers, the ecclesiastical ceremonies noted in parish records served as *proxies* for the underlying births, deaths, and onsets of cohabitation. It must always be remembered that the events in parish records are not the same as the underlying demographic events, e.g., a baptism is not a birth. With that caveat, a family reconstitution should provide information on the dates of birth, marriage, widowhood, remarriage; dates of the birth of children; and dates of death for individuals. It is possible in principle to continue such linkages across succeeding generations, or across collateral lines. Historians and demographers can examine family reconstitutions for patterns of fertility, mortality, and nuptiality, and to a limited extent those of migration in historical populations. The technique can be extended to the study of any other type of social or biological phenomena supported by the particular

dataset or other data such as medical, notarial, probate, or tax records that can be linked to it, e.g., heritability of cause of death, marriage patterns between social groups, fertility by social class, etc.

The parish registers on which family reconstitution relies are most commonly available in Catholic and Protestant Europe, and former European colonies that are predominantly Catholic. While many studies using parish registers focus on single communities, there have been some more ambitious efforts, most notably the study by Wrigley et al. (1997) of a large sample of parishes in English, and ongoing, major efforts to reconstitute large portions of the population of Quebec from its settlement in the seventeenth century up to the present (Bouchard, 1992; Desjardins, 1998). Parish registers have also been used in historical demographic studies of the Philippines (Doeppers and Xenos, 1998) and Latin America.

Related Methods and Expansions

Parish registers are by no means the only source that allow for the reconstitution of individual life histories and family pedigrees by record linkage. In recent decades, researchers have identified a variety of other sources from other societies that also allow for family reconstitution. In some cases, they provide information not normally available from parish registers, e.g., on household composition.

Genealogies

Genealogies are records of the linked lives of persons related by consanguinity and affinity and can, like reconstituted families, be used to extract demographic information. They were especially important for early historical demographic studies of China and Korea, because many lineages maintained them for ritual and other use. These retrospective family genealogies are often very selective, may not be representative of the broader population (Campbell and Lee, 2002). Aristocratic and wealthy families and lineages are more likely to be recorded than those more characteristic of the population. Within genealogies, persons of high status are more likely to be remembered, and those who die early, never marry, or otherwise do not leave descendants are more likely to be forgotten. In East Asian genealogies, males are more likely to be remembered than females. Females may be less well remembered if they have fewer male children of consequence with progeny, so that events linked through females are likely to be lost (especially if the females were in informal liaisons with the males of the lineage).

Certain databases of reconstituted families produced from genealogies nevertheless have proven very valuable. One of the largest and best known is the Utah Population Database (Bean, 1990). It was originally constructed from family genealogies compiled by Mormon families in Utah and neighboring areas from the nineteenth century onward. Another prominent genealogical source are the *Ortssippenbücher* (local books of family histories) of some German regions, compiled by local genealogists from parish registers in the early twentieth century primarily to demonstrate the ethnic purity of families. These are genealogies of the common folk (but of course selective as their purpose indicates), and have been used for demographic estimation (Knodel, 1988). In China, the Qing Imperial Lineage genealogy was compiled by a government office and covered all the descendants of the great-grandfather of the founder of the Lineage from the seventeenth century to the beginning of the twentieth century. Because the data were compiled prospectively, not retrospectively, they do not suffer from the limitations of other Chinese family genealogies. These data have been used extensively for demographic estimation (Lee et al., 1993). Compared to other Chinese genealogies, these data record daughters much more completely, and provide much more detail on the social and economic status of adult males.

Civil Vital Event Registers

Civil registers of vital events have the same potential as parish registers. They are intended to cover all faiths in a civil jurisdiction, but they may underreport some population segments such as vagrants or the poor. In some regions, civil registers can serve as a continuation of earlier parish registers and are especially valuable if secularization progresses and observation of ecclesiastical ceremonies declines.

Population Registers

Historically, civil and ecclesiastical population registers were listings of the inhabitants of residential units. They have the advantage of preserving the identity of the residential unit (usually 'households') within which the demographic events occurred, although just what that unit was is itself often problematic, since actual and legal residence might be confused, and even long-term out-migrants might sometimes be continued in the listings. (Such continuation is not unknown in some parish records as well, e.g., births to out-migrant former inhabitants.) Some registers were compiled at fixed intervals. Other registers were compiled on a continuous basis, with entrances into and exits from the household records as annotations of a single entry. Registers accomplish what is most difficult in family reconstitution, namely the nominal data linkage within and between individual lives, because local recorders presumably knew the identities of the persons and would not ordinarily confuse one individual with another who had the same name. Thus, the families discernible in population registers are not so much reconstituted as preconstituted. The most ambitious use of population registers has been in comparative studies of Europe and Asia (Bengtsson et al., 2004; Tsuya et al., 2010). The longitudinal, demographic, and household data collected from population registers are perhaps best understood as the historical analogue of data generated by contemporary Demographic Surveillance Sites like the ones that are part of the INDEPTH network (Sankoh and Byass, 2012). The ongoing release of data from population registers and INDEPTH sites raises the prospect of comparison between historical and contemporary populations.

Population Registers Updated at Fixed Intervals

Population registers updated at fixed intervals resemble annual or triennial censuses in terms of organization and content. Each new update described the population at a specific point in time.

While such registers can be treated like cross-sectional data and analyzed with the same methods used for census data, they differ from censuses in that individuals and families may be followed from one to the next. The occurrence of vital events in the interval between updates is reflected in an annotation, or sometimes implied through changes in household membership or individual characteristics. The longer the interval between updates, the more uncertain are the precise dates of the events. These registers are typically analyzed by application of discrete-time event-history techniques.

The best-known such registers are from East Asia. The first such historical population registers to be used for demographic analysis are the annual household registers that have been preserved for a number of communities from Tokugawa Japan *c*.1650–1868 (Hayami, 1969; Smith et al., 1977). Triennial registers covering a large number of communities in eighteenth- and nineteenth-century northeast China have also been transcribed into databases, analyzed (Lee and Campbell, 1997), and publicly released (Lee et al., 2010). Triennial registers have also been transcribed and analyzed for several Korean communities before the twentieth century (Lee and Park, 2008)

Continuously Updated Population Registers

In household registers compiled on a continuous basis, the timing of vital events and movements into and out of the household are recorded precisely. The best known of these registers are the ones compiled in Japanese-occupied Taiwan *c*.1904–45 (Wolf and Huang, 1980), but registers were also kept in some European countries, e.g., Belgium (Gutmann and van de Walle, 1978) and Italy (Kertzer and Hogan, 1989). Data from these registers are typically analyzed using continuous-time event-history techniques, most commonly Cox regression.

In some European contexts, linkage of multiple sources has produced demographic databases that resemble these continuous registers. For example, ecclesiastical population registers such as Swedish catechetical records and Italian *Libri status animarum* (literally, 'Book of the State of Souls') that recorded household and individual characteristics every year have been linked to parish registers that provide dates of baptisms, marriages, and burials that took place between annual updates.

Censuses

Construction of large demographic databases from historical censuses and advances in automated record linkage now make possible the linkage of individuals across censuses, and the reconstitution of families. Until recently, efforts to follow individuals from one census to another were mostly unproductive because censuses were decennial or at best every 5 years, transcribed samples only covered small geographic areas, and geographic mobility was high. Transcription of the entire 1880 United States census, availability of name indexes for censuses up to 1940, and advances in automated nominative linkage, however, have recently led to renewed efforts to create longitudinal data from United States censuses (Ferrie, 1996; Ruggles, 2006). For the 1850 through 1930 United States censuses, samples of individuals linked to the 1880 census are already available at the Integrated Public Use Microsample Series (IPUMS) Web site.

Methods of Family Reconstitution

The work of family reconstitution was from its inception strongly dependent on the paleographic and historical skills and intuition of the scholar. The earliest efforts were done by hand, starting with a marriage record; then attempting to find the burial and any remarriage records of the spouses; then the baptismal records of the children; and then the marriages and deaths of those children. Such data were entered on a 'marriage fiche' or 'family reconstitution form' for later collation and analysis. Account had to be taken of the literacy of scribes, variations in spellings of the same names, variations in standardization of surnames, and of course the completeness of the records themselves. Later attempts were assisted by computers, but final judgments often still depended on intuition in deciding between two or more equally plausible linkages. Efforts have been made to completely automate the linkage procedure, including the use of mathematical programming methods to resolve ambiguities, although it is not clear whether the algorithms themselves may not simply substitute new for old biases (Wrigley and Schofield, 1973; Bouchard, 1992). It is difficult to know when the correctness of the nominal links in a dataset has been maximized, especially when data are scanty or contain errors. For example, if surnames are often omitted in the parish documents, and especially if the stock of first names is small (e.g., 'John married Mary, 1 June 1712'), the number of alternative linkages can be very large because many Johns may have married Marys on that date. In principle linear programming methods can be used to obtain the best solution, one that maximizes the density or quality of linkage, but that solution may not be historically correct. Estimates of central tendency (e.g., the general fertility rate) will not be biased by such presumably random error, but variances will be, as will be any associations with other variables if guesses are more likely to be bad for some classes of persons. The results of nominal record linkage may be compared to population registers, but population registers also have problems of accuracy. Such problems of optimizing linkages are of course less when data are detailed (e.g., Swedish parish and population register records) or contain ethnographically validated clues to linkage (e.g., interfamilial patterns of godparenting in some South Slavic contexts wherein children of a marriage tend to have the same godparents, who also serve as marriage witnesses, etc.).

Limitations of the Technique

Although a powerful tool, family reconstitution has important limitations caused by missing data. Some stem from the nature of the sources.

Data Quality and Coverage

While some parish records (e.g., Florence, Istria) go back to the fifteenth century, most do not commence until the sixteenth, and many are not reliable until the eighteenth century. Civil event and population registers are generally no older than the nineteenth century, but ecclesiastical registers are often as old as the corresponding event registers. *Libri status animarum*

(Book of the State of Souls) were only irregularly kept in many areas, and all ecclesiastical records were subject to variations in quality depending on the abilities and dedication of the recording priest, attempts by higher authorities (both ecclesiastical and civil) to collect sufficient and standardized information, and the vagaries of copying and preservation. Ecclesiastical records are known for Catholic and Protestant populations but seldom for Orthodox Christians (not to mention Muslims, Jews, or others). Thus in areas of mixed religion, e.g., in nominally Catholic Croatia or parts of Bosnia, large non-Catholic proportions of the population would not be included in the data and investigation of regional patterns would be hampered. Remarkable discontinuities in the data can occur in periods of shifts in religious adherence, as e.g., sharp swings between conformity and nonconformity in English parishes, or the widespread conversion of Catholics to Islam in the western Balkans. Similar problems would arise in using missionary records outside of Europe and the Americas. *Civil* event and population registers are by their nature relatively independent of religious bias, although they may miss subpopulations whose members for other reasons are excluded or otherwise underregistered.

Statistical Biases Caused by Sample Selection

Probably the most serious problems for family reconstitution are selection bias and truncation, issues addressed early by Henry (1967).

Selection by Data Quality

Where data are in general of acceptable but varying quality, there is an inherent tendency to want to analyze records that are only of the best quality. The socioeconomic condition and demographic regime of a part of a population that has good records may be quite different from those of another part that has poor records. Analysis limited to only the best data may give a misleading picture of the whole, either with respect to entire parishes or to subpopulations within parishes. This kind of selectivity bias is similar to that experienced in the analysis of genealogical data.

Selection by Migration

Because the work of linkage is so tedious, even with computer assistance, most reconstitutions have been limited to single parishes. Out-migration from such parishes will ordinarily go unremarked in parish records, leading to the truncation and censoring problems described in Section Truncation and Censoring. Since the kinds of persons who complete their lives within a parish may be quite different from the kinds who leave it, building a demographic picture of a parish based on completed lives may be misleading. These and similar problems (see below) can be partly overcome by analysis of a set of contiguous parishes, especially if migration tended to be short range. Migration effects may be powerful where migration flows were strong (Kasakoff and Adams, 1995). Reconstitution data have been used to examine migration per se (Bideau and Brunet, 1993). Since population registers typically provide dates of entry and exit into a population for migrants, they can also be used to study the characteristics of in- and out-migrants.

Truncation and Censoring

In the absence of linkage of parish registers to other sources during family reconstitution, the time actually spent in a parish by a person who was not born in it or did not die in it may be unknown, and thus the time at risk of some demographic event may not be known. Many demographic measures cannot be properly estimated if time at risk is not known. For example, a woman may have had recorded births but no recorded death. The amount of time she was actually at risk of having the next birth cannot then be accurately estimated. Thus, the fertility of women at her achieved parity or at ages higher than that of her last recorded birth cannot be estimated accurately. For example, estimating the total fertility rate for the population would demand knowledge of the age-specific fertility rates by the usual 5-year age groups or by single years, and the loss of information on some women who died without record within such spans would deflate the denominators of the rate calculations.

In general, observation on individuals at risk of some event is said to be truncated if the size of the cohort at risk to which the individuals belong is unknown and censored if the number of individuals at risk is known but the events are unobserved or if observed events are recorded only in time intervals instead of accurately. Examples are (1) death records lacking age so that date of birth is unknown and the number of persons in the birth cohort cannot be recovered from birth records (truncated on the left); (2) death records with age recorded but birth records unavailable so that information is obtained only on persons who died at each age, not on those who survived that age (truncated on the right); (3) no marriage records but death records with age information showing survival and marital status so that the birth cohort size is known but the date of marriage is not (censored on the left); (4) birth and marriage records but no information on death so that observation ceases on the date of marriage (censored on the right). If statistical methods take censoring into account, censoring induces no bias in the computation of rates or probabilities of occurrence of an event, or in event-history analyses. By contrast, truncation does induce such bias. As a general rule, the onset or cessation of observation of an individual at risk should not be correlated with the event of interest.

Solutions to the problem of missing data in sets of life histories are various but problematic. They include using the occurrence of another event to the same individual (e.g., next births if interest is in mortality), random censoring, occurrence of an event to a close family member (thus implying continued residence and at least potential registration of an event), or statistical imputation of the censoring point, etc., (Hammel, 1993; Trussell and Guinnane, 1993). Another alternative is to make use of population registers or other sources that record entrances and exits into the population, thereby allowing for the individuals at risk of an event at each point in time to be identified with some precision (Bengtsson et al., 2004; Tsuya et al., 2010).

Bias from Delays in Recording

Bias may also be created by delays in the recording of demographic events or in the ceremonies that recognize them. An individual may die or move before an event is recorded and therefore be missed. Such delay is especially problematic for

births and infant deaths. If the date of recording is accepted as the date of birth, long delays will make infants seem younger than they are, biasing any age-related computations. If an infant dies before it can be baptized, there will be no record of the birth, and often there will be no record of the death since unbaptized infants often received no formal burial. If the death is recorded and an age at death is given, the date of birth can be imputed and thus recovered. If death is unrecorded, mortality may be underestimated. Where both birth and death are unrecorded, infant mortality will also seem to be lower than it really is. Since in many historical populations up to a third of infants died in their first year, and half of those died in their first month, such statistical biases can be very important.

Prospects

The most promising outlook for family reconstitution and related techniques includes the extension and elaboration of computer-based programming methods for rigorous and testable nominal data linkage; the combination of multiple data sources such as parish event registers, population registers, tax and notarial records, and most recently historical censuses, to increase the accuracy and scope of data; and the use of event-history techniques to overcome problems of missing event dates.

Summary

Despite difficulties imposed by the quality and coverage of the historical data and the possibility of biased inference, family reconstitution has given demographic and historical scholarship a remarkable window on the demographic past, unachievable by any other means. In so doing it provides information for much longer spans of time than do modern data and often for periods before any effects of industrialization or modernization have been felt. It thus allows examination of longer term trends under broader socioeconomic conditions, and like all historical enterprises allows scholarship to escape the constraints imposed by modern conditions.

Abstract

This article describes the principles and characteristics of techniques of indirect estimation used to derive estimates of demographic parameters from limited and/or defective data. The two broad classes of estimation techniques are described, giving examples. While the hope was that eventually these methods would be made redundant by improved data collection procedures, the suite of methods is still in widespread use half a century after they were first proposed.

'Indirect estimation' refers to the range of methods used by demographers to estimate rates of fertility, mortality (and, to a much lesser extent, migration) from data that are limited or defective, or both. The origin of the term stems from the pioneering work of the demographer William Brass in Africa in the 1960s. With the first censuses conducted after independence it was apparent, due to the observed deficiencies in the census data and the substantial incompleteness of vital registration systems of births and deaths, as well as the high levels of illiteracy and innumeracy in those populations, that direct estimation of rates of fertility and mortality, based on an analysis of the number of events occurring in a defined period of time and the exposure to risk of the population over that same period, could not produce robust and reliable estimates. Brass' important insight was that answers to simple questions, which might be better collected by enumerators and reported by respondents, could be manipulated by means of demographic models of fertility and mortality in conjunction with established mathematical relationships between demographic quantities to produce better estimates of the parameters of interest, and be robust to common patterns of error in the data.

A second category of indirect methods are those that seek to correct directly derived estimates of demographic parameters for commonly encountered errors in demographic data. Methods in this category use established relationships between demographic quantities to evaluate the consistency of the data, highlight possible sources of error, and adjust the directly observed rates accordingly.

Although these categories are rather different in their development and application, they nonetheless share the important characteristic of being based either on mathematically or logically robust relationships between different aspects of demographic data, or use model patterns of fertility, mortality, or migration to estimate or correct the parameters. To facilitate the process of demographic estimation by users who may not have extensive training in demographic estimation, parsimony of data requirements and simplicity of application by the end user are other important hallmarks of these methods.

While the methods derived by Brass and his collaborators have been developed, extended, and refined by many other demographers over the last 50 years, the approaches now in use are rooted in Brass' work, and still find use across the developing world. The material presented in this article cannot hope to provide even a summary description of all the methods that have been developed. Most of them were first written up comprehensively in *UN Manual X* (UN Population Division, 1983), the first systematic attempt to document the methods of demographic estimation from limited and defective data. Aspects of this work were revised and updated by Sloggett et al. (1994) and again (in the case of methods for estimating adult mortality) by the UN Population Division (2002). More recently, a project to revisit, revise, and update the canon of indirect methods of demographic estimation has been completed (Moultrie et al., 2013).

Indirect Estimation

The first category of methods of indirect demographic estimation seeks to produce more reliable and robust estimates of demographic parameters indirectly; that is, using information only loosely related to the parameters desired, and relying heavily on mathematical manipulation using demographic models to produce estimates of the desired parameters. These methods, all of which require very limited data as inputs, have been described by Ansley Coale – a collaborator with Brass in his work on African demography in the 1960s – as being akin to one of "making bricks with very little straw" (Coale, 2000: 55). The foundational logic of several of these methods is outlined below.

Estimation of Child Mortality

The classic, and still most widely applied, indirect method is what has come to be known as the Brass children surviving–children ever born method of estimating child mortality. The method, first set out in Brass (1964) and elaborated on in the seminal *Demography of Tropical Africa* (Brass et al., 1968), makes use of very simple summary data collected from women: how many children had they ever given birth to and how many of those were still alive, and transforms these inputs into estimates of the probability of a child dying between birth and a defined set of ages. Brass' insight was that the proportion of children dead of those ever born to women is closely associated with the age of the mother and the overall level of child mortality. Accordingly, using mathematical models of fertility and mortality, which exhibit strong regularities across a variety of demographic settings, Brass showed

Table 1 Brass' rubric for determining the ages to which the cumulative probabilities of mortality should apply, based on mother's age

Mother's age	*Best estimate of the age, x, to which the cumulative probability of mortality, q(x), applies*
15–19	1
20–24	2
25–29	3
30–34	5
35–39	10
40–44	15
45–49	20

how to convert these proportions of dead, controlling for the age of the mother, into cumulative probabilities of child mortality by age x, $q(x)$. Specifically, he showed that these proportions of dead could be mapped with some robustness (considering the poor quality or limited nature of the original data used as inputs) onto cumulative probabilities of death as shown in Table 1.

While Brass' approach has been refined and improved upon several times since its first exposition, the single most important contribution to the method was Feeney's (1980) observation that when mortality cannot be assumed to be constant over time, approximate reference dates could be put on the estimates of cumulative probabilities of mortality from different age groups of mother by assuming that changes in mortality are approximately linear over time.

A further refinement was to assume that the age pattern of mortality in a given setting follows a constant shape, with the level of mortality changing over time. This assumption, in conjunction with the Brass relational logit system of life tables, allows those different estimates of child mortality to be further converted into estimates of a single parameter, for example, $q(5)$, the probability of death before age 5, and for those estimates of the same parameter to be located in time using Feeney's approach, thereby allowing the identification of an approximate trend in mortality over time.

An example of the application of the method is presented in Figure 1, and shows the estimates of under-5 mortality in Malawi from the 1987 Malawi Census. Estimates of the same parameter from the United Nations Population Division are shown for comparison. A commonly encountered bias in the indirect method is indicated by the last data point. This estimate is derived from the reports of children ever born and children surviving from women aged 15–19 at the time of the census. The children of women who give birth at very young ages are more likely to die than children of women who give birth at older ages, resulting in the suggestion that child mortality in the country may have been increasing in the period just before the census. In most practical applications, this data point is ignored.

As Hill (2001: 3462) has noted, "[t]he Brass method and the developments of it have been very widely applied. It revolutionized knowledge of mortality conditions, particularly in sub-Saharan Africa but also in Latin America. It also gave rise to a concerted effort to find indirect estimation methods for adult mortality and migration. As such, it has proved one of the most influential ideas of demography." More recently, however, the method's applicability has been compromised by the spread of the HIV epidemic in sub-Saharan Africa. Most crucially, the epidemiology of HIV means that one of the central underlying assumptions of the method – namely the independence of the mortality of mothers and their children – is violated. Significant effort has been expended in recent years to further modify Brass's approach to accommodate the effects of HIV, largely without success. Even with the most promising approach developed so far, proposed by Ward and Zaba (2008), difficulties are encountered if the level of HIV prevalence in the population has changed over the preceding 15 or so years.

Estimation of Adult Mortality

Following the success of the Brass method for estimating child mortality, similar approaches were developed by Brass and his colleagues to estimate adult mortality using responses on the proportion – by respondents' age – of their mothers and fathers, spouses, and siblings who are reported to have died (respectively, the maternal and paternal orphanhood methods, the widowhood method, and the siblinghood method). The last of these has found particular use in the estimation of maternal mortality, and in the estimation of adult mortality from data collected in surveys where the sample size is typically too small to produce reliable estimates of adult mortality but, by asking about the survival of (typically in developing countries) relatively large numbers of siblings, allows mortality rates to be estimated.

As with the Brass children ever born–children surviving method, the robustness of the widowhood and orphanhood methods has been somewhat compromised by the effects of HIV/AIDS, although a simple adjustment has been proposed by Timæus and Nunn (1997) to compensate for this. In addition, problems with the application of the orphanhood method have been identified in many countries where adult death rates are high and fostering of the children of dead adults is common; in these situations, it is not uncommon for respondents to report on the vital status of their foster, rather than their biological, parents, resulting in an underestimation of mortality.

Estimation of Migration

Attempts have been made (Hill, 1987b; Zaba, 1985, 1987) to devise simple questions that can be asked in censuses that can be used to estimate migration in a similar fashion to the methods outlined above. These methods have not found widespread use, and doubts persist as to their robustness.

Estimation of Fertility

Estimates of trends in fertility can also be derived using indirect methods. The age structure of a population contains information that allow past trends in fertility to be measured. The population enumerated at a point in time of a given age, x to $x + 1$, represent the survivors of births that must have occurred x to $x + 1$ years previously. If the population can be assumed to be closed to migration, or if migration is negligible, an estimate of the mortality of successive cohorts of births allows one to estimate the number of births in preceding years. Furthermore, since it is possible to back-project the entire population, or that of women of reproductive age, to each preceding year using the same approach (or more simply, by assuming that the population has grown exponentially at a specified rate), it is possible to derive an estimate of either the crude birth rate or the general fertility ratio for approximately 15 years before the enumeration. (The limit of 15 years is placed to avoid the potential for in-or out-migration of young adults to bias the back-projected estimates). Despite, or perhaps because of, its simplicity, the method as outlined above has not been particularly useful, not least because it cannot produce estimates of age-specific fertility rates or of the total fertility rate.

This last limitation was addressed with the development of the 'own-child' method of fertility estimation (Cho et al., 1986). The method, further refined by Avery et al. (2013), relies on the ability to link children enumerated in a census in a household to their mothers present in the same household, and to thereby establish the mother's age at the time the child was born. Complex algorithms have to be employed to perform the matching, and those children whose mother cannot be identified in the same household have to have an appropriate mother's age imputed to them. Where children almost invariably live with their parents, the extent of the imputation required may be quite small; where fostering of children, or cohabitation in extended family groups, is widespread, the effects may be rather greater.

Recently, an alternative approach for estimation of fertility using reverse survival techniques has been proposed by Timæus and Moultrie (2013). This method has the advantage of providing the metrics desired (age-specific and total fertility rates) but avoids the issues associated with having to link children to their mothers by assuming that the shape of the age-specific fertility changes in a systematic and gradual fashion over time.

Consistency Checks

The second category of indirect techniques are those that rely on comparisons of two slightly different measures related to the same demographic parameter, and using the results to derive more robust estimates of that parameter.

Fertility

The Brass P/F ratio method, also developed by William Brass, is one such example. Brass had hypothesized (and evidence suggests that the hypothesis is generally correct) that, with census data on fertility, two specific errors frequently manifest themselves. The first relates to women's reports of lifetime fertility. Brass argued that older women's reports of lifetime fertility would tend to be biased systematically downward, particularly in very high fertility, and less literate or numerate environments, as a result of women neglecting to report dead children as such, or as a consequences of a failure to accurately estimate the exposure to risk. Conversely, he argued, younger women's reports of their lifetime fertility would be more accurate.

The second error hypothesized by Brass was that while women's recent reports – that is, collected on the basis of the number of births in the preceding year, or women's reports of fertility in a defined period of time – are frequently underreported, this underreporting is mostly independent of the age of the respondent. Consequently, while the level of fertility implied by direct estimates from the data may be too low, the shape of the fertility distribution would remain substantially correct.

Brass observed that if fertility had been constant, the cumulated period fertility up to a given age should be equal to the lifetime fertility of women of that age. Further, since

the lifetime fertility of younger women is presumed to be reasonably accurate, the ratio of lifetime to cumulated period fertility at younger ages provides a basis for adjusting the observed fertility schedule. The trend in these ratios by age of respondent also provides an important diagnostic of recent trends in fertility and possible errors in the data (Brass, 1975).

While the method has been in use almost without modification since it was first proposed, a significant refinement of the model by Zaba (1981) and Booth (1984) in the form of the relational Gompertz model (described in detail by Moultrie (2013)) allows the assumption of constant fertility to be relaxed. While this model is computationally rather different from the Brass *P*/*F* method, it is based on the same underlying logic of comparing lifetime and recent fertility to adjust the observed fertility schedules.

A number of other methods based on the *P*/*F* approach, allowing for estimation of fertility from two sets of census data have been derived (UN Population Division, 1983; Zlotnik and Hill, 1981). While these methods are highly sensitive to differential errors between censuses in recording lifetime fertility, an advantage is that they allow the assumption of constant fertility to be relaxed. These have all been recast as variants of the relational Gompertz method in the updated manual of indirect techniques, *Tools for Demographic Estimation* (Moultrie et al., 2013).

Adult Mortality

Indirect methods based on consistency checks have played an increasingly important role in the estimation of adult mortality. While the denominators used to estimate adult mortality rates can be sourced from census data, the numerator (that is, the number of deaths by age) comes from either a vital registration system, or – quite commonly – answers to questions in the census about the number of deaths that occurred in each household over a defined period before the census. Both sources of the numerator are prone to underreport the number of deaths, either because the vital registration system is incomplete or because not all adult deaths occurring in a household in the defined period are reported accurately.

Two similar, but nonetheless distinct, methods have been developed to correct the recorded or reported numbers of deaths for incompleteness. The first is the generalization of the Growth Balance method, first described by Brass (1975). Brass' original formulation assumed that the growth rate in the population had been stable for an extended period of time and that migration was negligible. Under these conditions, the rate at which people enter any open-ended age interval ($a+$) is equal to the sum of the (stable) population growth rate and the death rate of those in that age interval. However, this death rate is usually understated as a result of not all deaths being accurately recorded or reported. Brass' insight here was that if the completeness of death recording or reporting was constant with respect to age, the observed death rate in the open-ended interval $d^{o}(a+)$ could be expressed as the product of the actual death rate in the interval, $d(a+)$ and the proportion of deaths, c, that were correctly recorded or reported.

Hence, mathematically,

$$b(a+) = r + (1/c)d^{\circ}(a+)$$

where, in addition to the terms defined above, $b(a+)$ is the rate at which people enter the open interval, $a+$, which can be derived from the stable population age structure alone, and r is the stable population growth rate. In this formulation, then, there is a linear relationship between b and d, with the intercept being given by r, and the slope by the reciprocal of the completeness of death registration, c. With this estimate of c, the true estimate of the death rate in the open interval can be derived, and hence the reported or recorded deaths can be adjusted for the extent of underreporting.

In a major advance, Hill (1987a) extended Brass' idea and showed how it could be generalized to populations with unstable, or variable, growth rates using data from two censuses. Hill's generalization, termed the General Growth Balance method, further allows for the possibly differential completeness of the two censuses to be taken into account in estimating the level of completeness.

The second approach, developed by Bennett and Horiuchi (1981, 1984) and termed the 'Synthetic Extinct Generations' method, relies on the observation that, in a population closed to migration, the number of people alive in the population aged a and over must – since everyone must die – equal the number of deaths that will occur in the future of people aged a and over. In a stationary population (that is, one that has a constant birth rate equal to a constant death rate, and hence with a growth rate of zero), this number of future deaths will also be the number of annual deaths of those aged a and over. Bennett and Horiuchi further showed that this reasoning and their method could be generalized to nonstable populations where the growth rate in the population is not zero, using data from two censuses.

An example of the application of this method is presented by Dorrington (2013) using data from the 2001 Census and the 2007 Community Survey in South Africa. The results are shown in **Figure 2**. Although the model life table used to smooth the results allows for the effects of AIDS on mortality, the fit is not particularly good, but nonetheless is much better than those produced when using a life table that does not incorporate the effects of AIDS.

There is some debate as to which of these two consistency-based approaches to estimating adult mortality is preferable. Hill et al. (2009) suggest, based on the results of a series of simulations, that combining the two methods, using the General Growth Balance method to estimate the change in completeness of coverage of the data from the two censuses, and then using this as an input in the Synthetic Extinct Generations method produces more robust results than either method applied separately. However, Dorrington and Timæus (2008) observed that this was not the case in populations severely affected by AIDS.

Future Directions

Indirect estimation methods were not intended as a long-term replacement for direct estimation of demographic rates from census and vital registration data; the methods were derived as

Figure 2 Estimation of male adult mortality in South Africa, applying the synthetic extinct generations method to data from the 2001 South African census and the 2007 Community Survey. a stopgap way of estimating rates from limited and defective data, with the hope that, in time, improvements in census data collection and improving completeness of vital registration systems would render the methods obsolete. Unfortunately, progress in this regard in developing countries, and especially in sub-Saharan Africa, has been slow. Consequently, the canon of indirect methods still plays an important role in demographic estimation where the quality of data remains poor, or – increasingly – in situations such as in the demographic estimation of parameters for small areas where the data are too sparse to permit direct calculation. With much greater quantities of data now available, even from developing countries, work still continues on validating, refining, and improving the suite of indirect methods using simulation techniques as well as comparison with gold standard data. A recent example is the work of Masquelier (2013) in his investigations of the nature of biases in the estimates of adult mortality produced by the siblinghood methods.

Demographic Techniques: Inverse Projection

Abstract

Inverse projection, designed in the late 1960s by Ronald Lee, is a method for reconstructing populations where vital registration data are available but age details are scarce and population census is lacking or unreliable, as it is often the case of historical populations. Since its introduction, several modifications have been made to Lee's original procedure in order to address some of its shortcomings and to make the procedure suitable to the existing sources. Inverse projection and its developments have produced important innovations in the field of population reconstruction.

Origins

Inverse projection (IP) is a method for reconstructing populations where vital registration data are available but age details are scarce and population censuses are lacking or unreliable, as it is often the case of historical populations. The technique has been devised by Ronald Lee in the late 1960s as part of his PhD dissertation, which was a study of the broad macro determinants and consequences of aggregate population change in preindustrial England (Lee, 2004). It then appeared in an article published in 'Population Studies' in 1974. IP estimates accurate demographic indicators – life expectancy, gross and net reproduction ratios – and population age structures just using time series of deaths and births and an estimate of the initial population size. The projection is hence logically inverted because instead of using age-specific rates to estimate totals of births and deaths and population age structures, as conventional projection techniques do, it derives age-specific rates and population age structures from counts of births and deaths.

The inverted projection routine offers a solution to the problem of analyzing the demographic characteristics of past populations in the case of lack and incompleteness of sources. As in the case of family reconstitution – the microdemographic technique devised by Louis Henry in the 1960s – IP is suitable to the available documentation for past populations because it uses parish registration data, which for European countries before the nineteenth century are often more available than data on the size of the population and its age and sex structures. However, unlike Henry's nominative technique, IP requires only aggregate data thus overcoming some important limits that result from the family reconstitution and that were at the center of a lively debate among scholars of the time. 'Moving families', which may differ from 'stable families' for social and demographic characteristics, are difficult to detect and thus they can escape the family reconstitution. Hence given the difficulty of extending the reconstruction to all households in the village studied, results from the nominative technique may result unrepresentative. Other obstacles refer to the inability to aggregate results related to single villages and to consider these as representative of wider areas. Furthermore, although researchers today can avail themselves of computer programs for linkage, it must be recognized the enormous amount of energy needed to reconstruct a village made up of only a few families. Instead, with little effort, IP is able to reconstruct the demographic history of entire, even large populations over long periods of time, producing surprisingly accurate demographic indicators, by requiring only aggregate data. As Lee has pointed out (2004) "Some good ideas just don't work out in practice, while other ideas that seem to be based on very questionable assumptions, surprise us by working better than one could reasonably expect. Inverse Projection certainly falls in this second category". However, it must be said that historical demographers today are broadly in agreement in considering the aggregative technique of IP and the nominative reconstitution of families as two different techniques to be used profitably in a quite complementary way.

Method

In the study of past populations, the lack of complete data inevitably leads to the use of techniques that rely on models. This is also the case of IP that, in fact, presupposes the use of age schedules of mortality, fertility, and migration. To initiate the projection, IP requires the total population at the beginning of the period, an initial age structure of the population (obtained from either a census or a model), and counts of births and deaths for each interval. Under the hypothesis of closed population, to project the initial population at the subsequent instant, deaths occurred in the time interval must be subtracted for each age. But, since only the total number of deaths is known, this total is distributed by age through a series of probabilities of death that, applied to a given age structure, gives precisely the number of deaths observed in the considered time interval. This particular series of probabilities is determined by linear interpolation between two adjacent age schedules of mortality chosen from a single-parameter family of life tables. An adjustment factor, k_t, which is proportional to the difference of the two age schedules chosen as standard, locates the current series of probabilities of death. This variable can be viewed as an index of the force of mortality.

By removing the hypothesis of closed population, the procedure requires the knowledge of the total population not only at the beginning, but also at the end of the period considered, or, better, at instants subsequent to the initial. The

projected total, derived just adding the counts of births and subtracting the counts of deaths, is subtracted from the observed total population to obtain an estimate of net migration. Net migration is then apportioned equally among the intervening periods. In case of long periods, net migration is apportioned among the intervening periods through a more sophisticated solution based on the amount of the population and the number of intervals included in the period. Once the number of migrants in each interval is determined, they are distributed by age according to a standard pattern of age-specific rates.

Once the age distribution of the population is estimated, it is then possible to estimate the most important measures of mortality and fertility. The gross reproduction ratio is estimated from the number of birth, the age structure of the population, and a normalized age pattern of fertility which changes over time by a proportional factor, f_t, at all ages. This variable can be viewed as an index of the force of fertility. Models of fertility, therefore, affect only the estimates of the relative measures, since they are not used to estimate the number of births that are already known at the beginning of the procedure.

Theoretically, IP can generate estimates of nuptiality measures. Of course, in order to obtain these estimates, it is necessary to consider as inputs an age schedule of marriage, the marital status of the initial population, and the time series of marriages. But apart from the objective (and not negligible) difficulty to find these information for historical populations, IP that, also in this case, as for mortality and fertility, assumes a model of marriage rates with proportional changes over time at all ages, is not suitable to the analysis of a complex phenomenon such as nuptiality (Brunborg, 1976 cited in Lee, 2004; Breschi, 1990).

Over time, some extensions have been added to the original IP formulation. The first enhancement has been the extension of the number of age groups beyond age 55. The final open-ended group was in fact originally fixed at age 55 because computer was slow and expensive but it has been shown that this limit produces bias when life expectancy improves (Brunborg, 1976 cited in McCaa and Barbi, 2004). Another important enhancement was the implementation of annual projections in place of 5- or 10-year periods (Biraben and Bonneuil, 1986; McCaa and Brignoli, 1989). Also, the IP method is not well suitable to capture age patterns of mortality for particular conditions of mortality such as epidemics, famine, civil war etc. Mortality crises were frequent in historical populations and they often affected selectively the population, thus determining substantial changes in the age profile of mortality. These changes, however, are not captured by IP since the underlying hypothesis in the IP algorithm is that mortality varies over time only by an age-independent factor, which is proportional to the difference between two adjacent age schedules of mortality. Thus IP will produce estimates of the probabilities of death disproportionately high at younger and older ages, leading hence to a distorted reconstruction. A solution was to set a mortality ceiling considered normal for the study period. The number of deaths below this threshold is apportioned according to the IP method while the exceeding part is apportioned proportionally to the size of the population of each age group (Biraben and Bonneuil, 1986; McCaa, 1993).

Many applications have highlighted the extreme adaptability of the procedure to the available documentation. Its robustness with respect to the choice of age patterns of vital events and the initial age structure, guarantees a good stability of the estimates and therefore it is a great advantage for those who, due to lack of information, are forced to make arbitrary choices. Many studies have shown that any wrong choice of the age structure and the mortality model have only a negligible impact on the estimates of the various demographic indicators (Lee, 1974, 1985; McCaa, 1989; McCaa and Vaupel, 1992; McCaa, 1993). The differences in the estimates obtained with two different initial age structures are quite strong in the early cycles of the projection, but diminish rapidly as the projection continues. Wachter has shown (1986) that the weak ergodicity theorem is extendible also to IP. In the long run, vital rates determine the population, not its initial state. The population hence quickly forgets its past age distribution. With regard to the mortality model, the effects of different hypotheses are more modest than those caused by different initial age structures, but appear to be more persistent over time. On the other hand, IP requires good vital registration data. As shown by Brunborg (1976), and McCaa and Vaupel (1992), quality of data is the most important factor for successfully applying the method (McCaa and Barbi, 2004).

Thanks to McCaa (1989) and McCaa and Brignoli (1989), who devised the user-friendly program 'populate', the IP could be readily applied by several researchers around the world.

Developments

Back projection was developed by Wrigley and Schofield for their massive reconstruction of the population of England, 1541–1871, as a means of dealing with the closure problem (Wrigley and Schofield, 1981; Oeppen, 1993b). Most populations, over the long run, are not closed, and England is no exception. While forward IP takes into account authentic migration data, Lee's method cannot produce migration flows (Lee, 1993). Back projection seeks to generate migration estimates from a terminal age structure by backcasting the population against the flow of births and deaths. While it might seem commonsensical to begin with the best, i.e., most recent, data and project backwards, Lee argues that this ignores the weak ergodicity theorem. In Lee's words (1993), "the problem originates with the attempt to resurrect people who have died into the oldest age group, an attempt that is, in practice, hypersensitive to error". The Cambridge team used iteration procedures to settle upon a single series of best estimates. However, beyond the Cambridge team, back projection has attracted few proselytes.

Generalized inverse projection (GIP) responds to Lee's criticisms of back projection and broadens the method into an analytical system which exploits whatever data are available as well as a broad range of assumptions or constraints, including components derived from back projection (Oeppen, 1993a,b). Lee's IP and back projection may be seen in fact as members of a same class of constrained projection models. In the worst situation of data scarcity – i.e., in the back projection frame, when only series of births and deaths and the final population age structure are known – generalized inverse

projectionists argue that the method can endogenously estimate migration flows as well as population totals and age structures by using a standard nonlinear optimization algorithm which maximizes the consistency between assumptions and data. The starting age structure can be also estimated using a stable population assumption. Since there are more parameters to be estimated (migration and mortality) than empirical observations (death totals and age groups of the final population), additional assumptions and/or data are required. Despite its flexibility, GIP has to solve an 'ill-posed' problem because of the uncertainty of the uniqueness and stability of the final solution. In Oeppen's words (1993b), "The selection of extra targets is somewhat arbitrary, which is in part a virtue since it allows a researcher to use whatever is available, but it also makes the estimates dependent on these extra targets". Lee (1993) remains unpersuaded, arguing that "…one can easily construct an infinity of radically different trajectories of population size, net migration, fertility and mortality which exactly match the given data".

Trend projection (Biraben and Bonneuil, 1986; Bonneuil, 1993) reconstructs past populations using series of births and deaths but in the absence of any census count or age structure. Given a birth and death series, the method finds a single value for which the trend in life expectancy after the initial date of the burial series is equal to the assumed value before. The method works well for closed populations but is ill-suited to open ones.

The flexibility and the potentiality of the IP method could not be ignored by Italian demographers given the rich availability of historical record of parish data of exceedingly high quality. In Italy, the first attempt to reconstruct a past population using the IP method is the work by Marco Breschi (1990) who tried to trace the demographic evolution of Tuscany from 1640 to 1940. The case of Tuscany, where demographic-statistical documentation is particularly detailed, allows Breschi to fully exploit the method and to develop a first and experimental version of two-sex projections. Results from Breschi's reconstruction demonstrated that the growth of the population of Tuscany starting from the middle of the eighteenth century was probably due, as in the case of England, to a rise in fertility rather than to a fall in mortality.

Since Breschi's work, new flavors of the method were developed, on the one hand, to exploit all available information and, on the other, to overcome some limits of Lee's IP.

The *differentiated IP* (Rosina, 1993, 1996; Rosina and Rossi, 1993) arises from the richness of data available in historical-demographic sources of some Italian regions where the age at death is faithfully reported. The procedure is based on the distribution of death by big age classes or, more simply, by only two age classes: infant and adult ages. In this case, the age-differentiated version of IP takes into account two life tables which, following Lee's procedure, have to fulfill two constraints: the first life table has to be such as the probabilities of death, applied to the young population, yield the total number of deaths recorded for infants and children and the second one has to be such as the probabilities of death, applied to the adult population, yield the total of deaths recorded at adult ages.

The aim of the age-differentiated procedure is to overcome possible shortcomings, already mentioned in Section Method, deriving from Lee's original assumption about the estimation of the age structure of the mortality function which, as said, varies over time only by a proportionality factor, the k_t variable, which does not depend on age but refers to the time-independent differences between two life tables from the same family. This assumption can lead, in exceptionally low or high mortality conditions, to probabilities of death greater than one or less than zero! This matter is particularly important in the past when age-selective mortality crises shifted not only the level but also the profile of mortality. It has been shown (Rosina and Rossi, 1994) that the distribution of deaths by as few as three age classes leads to an improvement of the fit to the observed data of about 80%. The differentiated IP has more explanatory power than the original IP as demonstrated by Rossi and Rosina in the study on the transition in the Venetian area (1998). However, since the age structure of the initial population has to be consistent with the information on deaths by age, the differentiated version of IP is, on the one hand, more rigorous, on the other, due to the larger number of constraints, less flexible with respect to Lee's procedure. This feature, especially in single-year projections, with the occurrence of a heavy mortality crisis, may lead to impossible probabilities of death (Barbi, 1997). The features of the method and an overview of various applications are described by Rosina (2004).

To make the profile of the mortality function more sensitive to possible changes over time and to avoid estimates of 'negative' population or 'births' at adult or old ages, Salvatore Bertino (1995) suggested some others modifications to Lee's method. Of particular interest is a model that estimates the mortality function at each time through a recursive procedure. The adjustment factor at each time t, k_t, is still determined through Lee's technique but the mortality function at each time t is estimated through a linear combination of the mortality functions estimated at time $t-1$ and $t-2$ with coefficients respectively equal to $1 + k_t$ and $-k_t$. Furthermore, the procedure imposes some convenient limits to the probabilities of death in the extreme ages (besides the obvious limits of 0 and 1) and then the adjustment factor is determined in an iterative way. Unfortunately, the robustness of Bertino's idea cannot be assessed in practice because, up to now, no software has been devised to implement his formulas.

An innovative more recent algorithm is the *stochastic inverse projection* (SIP) devised by Salvatore Bertino and Eugenio Sonnino in (1995) and appeared in an article published on Mathematical Population Studies in 2003. This procedure reconstructs past populations through a microsimulation approach. First, similar to Lee's procedure, a linear variation of the mortality function between two life tables relative to the beginning and the end of the studied period is hypothesized. Additionally, it is possible to enter two additional models for dealing with years where unusual conditions of mortality prevailed. Then, it is assumed that each individual in the population follows, over the entire life span, a nonhomogeneous Poisson process with intensity equal to the force of mortality obtained by approximation from step 1. Assuming that all individuals behave independently from each others, the

Poisson theory allows one to calculate the probability that a mortality event occurring at time t is to be attributed to an individual of age x. Generating a realization of the random variable 'age at death', according to the probability distribution just determined, it is possible to assign, by simulation, an age of death to the individual. The procedure is replicated for all recorded deaths so as to obtain the distribution of deaths by age, which is necessary to project the population. Similarly, fertility statistics are also determined by simulation. Although methodologically different, both forward and backward projections are possible with the stochastic method.

Instead of a single deterministic solution as with usual reconstruction methods, the stochastic approach offers a set of different reconstructions for the same time t. Then, the average scenario and the variability in a population's evolution are also evaluated. The results of all these alternative simulations differ by chance only and are equally coherent because they are governed by the same data and models. A comparison between the behavior of the IP technique, the differentiated version, and the stochastic method in various simulated scenarios of exceptional mortality (Barbi, 1997) shows that the stochastic approach proceeds in a way, which closely reflects empirically observed patterns. The estimated probabilities of death are based not only on theoretical risks (the intensity of the Poisson process) but also on the proportion of the population at each age. This is a key point, especially in the reconstruction of small populations. The stochastic approach recognizes the eventuality that very few mortality events or even none may be attributed in some old age classes where individuals are few although their theoretical mortality risks are high.

Barbi and Oeppen (2004) compared the results from the GIP and the SIP in the back projection frame (when the terminal age structure of the population is specified) and showed that both the techniques reconstruct demographic scenarios coherently with recorded data. However, Lee (2004), while appreciates the stochastic approach because it provides an estimate of the uncertainty in the IP results, and Oeppen's generalized version because of its flexibility to incorporate demographic information that are available, does not see any advantage to running SIP backward and continues to be critic with respect to GIP when running in the back projection frame in the absence of input data on migration.

IP and its variations have produced important innovations in the field of population projection. Their strategy is to exploit specific existing documentation so as to lead to coherent demographic reconstructions. Desirable developments should look at an even more flexible approach that takes benefit of any bit of demographic information, a general model able "to cover situations in which one did not have full time series of births and deaths, and perhaps had more information of other kinds, such as censuses" (Lee, 2004). Toward this direction is the approach devised recently by Bonneuil and Fursa (2011, 2012). Combining the Lotka–McKendrick population model with stochastic optimization, the authors reconstruct the demographic dynamics, even by civil status, from partially missing or flawed demographic data. Abstract

Demographic rates may be computed for a calendar period or for a birth cohort, by age attained at the time of occurrence, or at the end of the calendar year of occurrence. Demographers keep track of this plethora of rates by means of a simple graphical device that has become known as the Lexis diagram. The purpose of this article is to explain this diagram and show how it can be of help in describing usage of rates in each particular analysis. To enable analysts to improve comparability, it also provides conversion formulas that can be used to compute selected types of rates from the ingredients originally intended for the computation of other rates. Methods to eliminate biases produced when standard procedures are applied to unsteady flows of births caused by major political events like wars are discussed.

The quintessential building block of demographic analysis is a set of occurrence/exposure rates computed by dividing the number of occurrences of a selected demographic event in a (sub) population into the corresponding number of person-years under risk. The event may be repeatable, which means that it may occur more than once in the life course of an individual, such as geographical moves and the birth of children. Alternatively the event occurs only once in a lifetime, such as a first birth or a first marriage, or at the end of life, namely death. For repeatable events, the occurrences recorded for each age group are divided by the total number of person-years observed in the same age group, and one gets quantities like births per 1000 woman-years at ages 30–34. For non-repeatable events, the occurrences in the age group are divided into the number of person-years observed among population members who have not yet experienced the index event, and one gets quantities like first births per 1000 person-years among childless women. Demographic rates may be computed for a calendar period or for a birth cohort, by age attained at the time of occurrence or at the end of the calendar year of occurrence. Demographers keep track of this plethora of rates by means of a simple graphical device that has become known as the LEXIS diagram. The purpose of the present Encyclopedia article is to explain this diagram and show how it can be of help in describing usage of rates in each particular analysis.

Demographic rates are computed according to different conventions in different countries, and some countries have changed their practice over time. This makes it difficult to compare series of rates across countries and sometimes over time. To enable analysts to improve comparability, we will also provide conversion formulas that can be used to compute selected types of rates from the ingredients originally intended for the computation of other rates. We also provide methods to eliminate biases produced when standard procedures are applied to unsteady flows of births caused by major political events like wars. Such biases only affect certain birth cohorts, but in the disturbed cohorts all ages are involved.

The LEXIS Diagram

The LEXIS diagram provides a visual representation of occurrences and exposures across age and time. Since age and time increase in lockstep, a basic ingredient in the diagram is the lifeline of a person, showing age plotted against time on a 45-degree line starting at the time t_0 of birth and at age zero. If an event occurs to the person at a given time t, the age $t-t_0$ of that person at the time of occurrence is the ordinate of abscissa t on the lifeline (Figure 1).

The LEXIS diagram pertains to the residents of a given territory. The start of a lifeline may be the birth on the territory. In that case, the lifeline begins at the horizontal axis. When a person immigrates at age x at time t, the lifeline starts at the point (t, x). The end of the lifeline corresponds to the death or out-migration by the person.

Major vital events (births, deaths, marriages, divorces) are typically recorded through a vital registration system, which provides breakdowns of events by the age of the persons concerned. Residents are periodically enumerated through

Figure 1 Lifeline of a person born at time t_0.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.31014-5

censuses, which record the date of birth (or the completed age on the census day) of the respondents. At least at the national level, censuses are sometimes updated every year on a fixed date, most often January 1, so that the distribution of residents by single year of (completed) age is usually available annually. The number of persons whose completed age at time t is i is the number of lifelines that cross the vertical segment $(t, [i, i+1])$. These persons were born between times $t-i-1$ and $t-i$.

Two events that occur simultaneously are located on the same vertical line in the LEXIS diagram. Two non-simultaneous events that occur to persons having the same age at the time of occurrence are located on a horizontal line. Two non-simultaneous events that occur to persons born at the same time are located on a 45-degree line.

The events that occur during a given period (e.g., a given calendar year) are located in a vertical strip, between the vertical lines corresponding to the beginning and the end of the period (Figure 2). Those that occur to persons whose age at the time of occurrence belongs to the same age group are located in a horizontal strip. Those that occur to persons born during the

(b) Events occurring during the same year to persons who had the same age in completed years at the time of occurrence (members of two cohorts). (c) Events occurring to persons whose age was in the same age group at the time of occurrence. (d) Events occurring during the same year to persons who attained the same birthday during that year (members of the same cohort). (e) Events occurring to persons who belong to the same cohort. same period (i.e., who belong to the same birth cohort), are located in a 45-degree strip.

Age

The exact age of a person on a given date t is a continuous variable. It is equal to the exact duration from the date of birth to date t. In most connections and in common language, exact age is grouped to take only integer values, however, and this makes age a discrete variable. We then refer to it as age at last birthday, or age in completed years, or completed age. The distribution of residents by age on a given date is a breakdown of the population by completed age. If the date is January 1 of year n, persons then aged i in completed years are the residents born during the year $n-i-1$.

Tables classifying the events that occurred to residents during year n by age, may be presented either by completed age at the time of occurrence or, based on the year of birth, by the age that has been or will be attained during year n. The events of year n that correspond to completed age i (as measured at time of occurrence) are located in a square of the LEXIS diagram. Those that correspond to the same year of birth i.e., to the same age i attained during the course of year n or, in other words, to the same completed age i on December 31 of year n, are located in a parallelogram with vertical sides. A third possibility that combines the two consists in retaining completed age but distinguishing persons according to whether the birthday they celebrated in year n fell before or after the occurrence of the event. When the latter distinction is made, the numbers of events refer to triangles in the LEXIS diagram, the lower triangle of the square concerns persons whose birthday in year n was before the occurrence of the event, the upper triangle those for whom it was after. Note that persons for whom an event was recorded during year n at completed age i were half a year older than those who had it recorded at attained age i on 'average' at the time of occurrence. The former had an 'average' exact age equal to $i+\frac{1}{2}$, the latter an 'average' exact age equal to i. (What we mean by 'average' here will be made clear later.) This half a year difference may be of some importance. For example, teenage fertility, defined as fertility below age 20 years, may differ by as much as 25% if age is defined in terms of completed age instead of age attained during the year.

Rates of the First and Second Kind

Suppose that one's interest focuses on a given demographic (or other) event. For each region in the LEXIS diagram where the data are available, the analyst may record the number of occurrences of the event in question. For repeatable events, one may also add up the lengths of all lifelines that intersect the given LEXIS region (or their projections on the time axis) to get the total person-years of exposure to the risk of occurrence of the event in question. The ratio between the number of occurrences and the latter exposures is the corresponding occurrence/exposure rate.

For non-repeatable events one can compute two kinds of rates. The rate of the first kind (or occurrence/exposure rate) is computed using lifelines interrupted at the time of event occurrence. Their denominator is again the 'total person-years exposed to risk.' A corresponding rate of the second kind (or occurrence/population rate) uses the same occurrences, but the denominator is computed in the same manner as for repeatable events i.e., lifelines are not interrupted at the time of event occurrence. If the non-repeatable event always terminates a lifeline, the rates of the first and second kind coincide and there is a single occurrence/exposure rate for the given region. This is of course the case if the event is death or out-migration.

Rates of the second kind are sometimes computed because the aggregate data do not provide the person-years exposed to risk but only the total number of person-years for the LEXIS region selected i.e., the person-years at risk plus the person-years for members of the population who are no longer at risk. A case in point is when first marriages observed in the relevant population segment are referred to the total resident population in the same segment, instead of only to the person-years for the never-married, perhaps because the latter exposures are not available by sex and single years of age on an annual basis. Another example arises when births of a given order are divided by the total number of person-years lived in the same population segment instead of only by the corresponding number of person-years for persons of the previous childbearing parity. This article is concerned with rates of the first kind. Rates of the second kind are discussed in a companion article, as is the connection between the two kinds of rates.

To avoid using many decimals, the rates are normally multiplied by a convenient factor like 1000, 10 000, or 100 000 before tabulation. If the factor is 100 000, such a rate is said to be computed 'per 100 000 person-years,' where for rates of the first kind the latter are years of exposure to risk.

A Mathematical Framework of the Study of Occurrence/Exposure Rates

Repeatable Events

Let us consider a person exposed between ages α and ω to the occurrence of a *repeatable* event E, and let us reason as if the person is not exposed to any other event (in particular, no migration and no death). Let $\lambda(x)\,\mathrm{d}x$ be the probability that E occurs to this person between exact ages x and $x+\mathrm{d}x$. Outside the interval (α, ω), $\lambda(x)$ is zero. Then function λ is called the risk function of the repeatable event E.

By the properties of a Poisson process, the expected total number of occurrences of E to this person is $\int_\alpha^\omega \lambda(x)\mathrm{d}x$. If we let $f(x) = \lambda(x)/\int_\alpha^\omega \lambda(u)\mathrm{d}u$, we can regard this as the density of a probability distribution with mean $m = \int_\alpha^\omega xf(x)\mathrm{d}x$ and variance $V = \int_\alpha^\omega (x-m)^2 f(x)\mathrm{d}x$. If the field of study is fertility and the event E is the birth of a child to a woman, the integral $\int_\alpha^\omega \lambda(x)\mathrm{d}x$ is called the cohort-completed fertility and is the average number of children per woman. The mean age at occurrence is called the mean age at childbirth.

Non-Repeatable Events

If the event E can happen only once in a lifetime, then $\lambda(x)\,\mathrm{d}x$ is the probability that E occurs to a given person between exact

ages x and $x + \mathrm{d}x$, provided it has not occurred by exact age x. According to standard single-decrement life-table theory (*see* Life Table), the probability that the event E does not occur to a given person before age $x > a$ is $\ell(x) = \exp\left(-\int_\alpha^x \lambda(u)\mathrm{d}u\right)$. The probability that event E occurs between ages x and $x+t$, given that it has not occurred before age x, is

$$ {}_tq_x = 1 - \exp\left(-\int_x^{x+t} \lambda(u)\mathrm{d}u\right) $$

The probability of ever experiencing E is $1 - \ell(\omega) = 1 - \exp\left(-\int_\alpha^\omega \lambda(x)\mathrm{d}x\right)$. Note that this probability is less than 1 if and only if $\int_\alpha^\omega \lambda(x)\ \mathrm{d}x < \infty$.

The density of the age at which E occurs, given that it ever does, is $\lambda(x)\ell(x)/[1 - \ell(\omega)]$. The mean age at occurrence is

$$ m = \alpha + \int_\alpha^\omega \frac{\ell(x) - \ell(\omega)}{1 - \ell(\omega)}\mathrm{d}x $$

The higher moments of this distribution are defined similarly. If the event E is death, considered from birth (which means that $\alpha = 0$ and ω is the maximum human life span) i.e., if the field of study is overall mortality, then the mean age at occurrence is called the life expectancy at birth. The quantity we have denoted $\lambda(x)$ is called the force of mortality at age x and $\ell(x)$ is the survival function at age x. If the event E is death considered only after a given age $a > \alpha$, the difference between the mean age at occurrence and a is called the life expectancy at age a; it is the average number of years remaining to a person still alive at age a.

If event E is first marriage below completed age 50, $1 - \ell(50)$ is the proportion ever married by age 50 and $\ell(50)$ is called the final celibacy. The mean age at occurrence is the mean age at first marriage (below 50).

If the event E is the birth of a child of order k ($k \geq 2$) to a woman and time is recorded not from the birth of the woman but from the date of birth of her preceding child, $1 - \ell(\omega)$ is the proportion who reach parity k among women reaching parity $k - 1$. This is also called the parity progression ratio from order $k - 1$ to order k. For $k = 1$, time is recorded from the birth of the woman or from any other suitable origin (e.g., the moment of marriage if the field of study is marital fertility) and $1 - \ell(\omega)$ is the proportion of women who have at least one child. The frequency of childlessness is $\ell(\omega)$.

Annual Record of Events for Both Time of Occurrence and Age at Occurrence

Rates

Tables classifying events that have occurred during one calendar year, say year n, by single year of age of the person concerned, may be established by squares or by vertical-sided parallelograms in the LEXIS diagram. We let the current value of age completed be the integer i. In both cases, we have to estimate the probability of occurrence of event E within a doubly annual figure. In the mathematical framework presented above, we face three difficulties. *First*, we do not have a single person to consider but a discrete cohort born during calendar year $n-i$ in the case of a vertical-sided parallelogram, or two consecutive discrete cohorts (born in years $n-i-1$ and $n-i$) in the case of a square. In the parallelogram, each member of the cohort is exposed to risk during exactly 1 year (unless the person dies or migrates), but in the square the members of the two cohorts are exposed to risk during periods of variable duration ranging from 0 (for those born close to January 1 of year $n-i-1$ or close to December 31 of year $n-i$) to 1 year (for those born close to January 1 of year $n-i$). Furthermore, the risk function $\lambda(x)$ may now well vary with the time of birth g, in which case we should rewrite the function as $\lambda(x, g)$.

Second, the statistical data available may not be the full individual-level information, which would consist of the date of birth of each person and the various dates of occurrence of event E if it happens to occur to that person. We typically just know the *total number* of events inside the parallelogram or the square and the corresponding exposures.

Third, since our mathematical theory was developed for a single event E, migration and death (or only migration if event E is itself death) complicate the situation. The total number of events recorded includes those occurring to in-migrants or to persons who die or out-migrate subsequently to an occurrence inside the region in the LEXIS diagram; migration and deaths are duly taken into account in the total number of residents classified by age at both year-ends. But in aggregate data the exact date of death, in-migration or out-migration of each person exposed to risk in the territory considered is not known. For these reasons, we will now reformulate our mathematical framework. We do it in two steps: first a simple one and second by a more sophisticated one.

First Simple Assumption: Constant Risk Function

Our simple reformulation holds for any kind of event, whether repeatable or not, and is as follows: Let us assume that the risk function λ is constant inside the age bracket concerned (exact ages i to $i+1$ in the case of a square, $i-1$ to $i+1$ in the case of a vertical-sided parallelogram). The probability that event E occurs is $\lambda\ \mathrm{d}g\ \mathrm{d}x$ for a resident who is born between times g and $g+\mathrm{d}g$ and whose exact age is between x and $x+\mathrm{d}x$, for every g and x inside the LEXIS-diagram region. Then the occurrence/exposure rate (of the first kind) is the maximum likelihood estimate of λ in the case of squares as well as of parallelograms. Let us furthermore assume that the number of entries due to in-migration, and exits due to death and out-migration, lead to a uniform balance: the net number of entries of persons born between g and $g+\mathrm{d}g$ when their exact age is between x and $x+\mathrm{d}x$ is $s\ \mathrm{d}g\ \mathrm{d}x$, where s is a constant.

As we already stated, net 'in-migrants' are supposed to have the same risk λ as the non-migrants. The quantity s can be approximated by $s_i^n = P_i^{n+1} - P_{i-1}^n$ inside a parallelogram with vertical sides on the basis of the numbers of residents at year-ends by single year of age. Here p_i^n is the number of residents of completed age i on January 1 of year n. (If event E is death, s_i^n is equal to $P_i^{n+1} - P_{i-1}^n - D_i^n$, where D_i^n is the number of deaths occurring during year n of residents born in year $n-i$.) If events are observed in squares, then s_{i+1}^n is an approximation to s_U in the upper triangle of the square, while s_i^n is an approximation to s_L in the lower triangle.

Vertical-Sided Parallelograms

When events are observed in vertical-sided parallelograms, the P_{i-1}^n residents on January 1 of year n, born in year $n-i-1$, who attain their ith birthday during year n, are all at risk during one year each, and the s net 'in-migrants' are at risk during half a year on average, so that the sum of exposures to risk is

$$R_i^n \approx P_{i-1}^n + \frac{1}{2}s = \frac{1}{2}\left(P_{i-1}^n + P_i^{n+1}\right)$$

The estimate $\widehat{\lambda}$ of λ is the observed occurrence/exposure rate $\widehat{\lambda} = VSP_i^n/R_i^n$, where VSP_i^n is indicated in Figure 3(a).

Squares

When events are observed in squares, we estimate the exposures to risk in each triangle of the square. We consider the upper and the lower triangle, one at a time. In the upper triangle, there are p_i^n persons in the population on January 1, or rather $P_i^n + \frac{1}{2}s_U$ persons who attain their $(i+1)$th birthday during year n and who are exposed between 0 and 1 year. If we introduce $m(G)$ as the average location inside year n of the birthdays attained during that year by persons born in year G, their average exposure to risk is $m(n-i-1)$. Total exposures equal $(p_i^n + \frac{1}{2}s_U)m(n-i-1)$. However, the $s_U/2$ net entries have an average duration at risk of $\frac{1}{3}$ year. The corresponding exposures must be deducted since they are unduly included in the previous total. Thus the total exposure in the upper triangle is

$$\left(P_i^n + \frac{s_U}{2}\right)m(n-i-1) - \frac{s_U}{6} \approx P_i^n m(n-i-1) + \frac{s_U}{12}$$

Since $m(G)$ is anyhow close to $\frac{1}{2}$ and s is small compared to p_i^n. In the lower triangle, $P_i^{n+1} - \frac{1}{2}s_L$ persons attain their ith birthday during year n. They are exposed during an average period of $1-m(n-i)$, and there are $s_L/2$ net entries with an average duration of $\frac{1}{3}$ year, leading to total exposures of

$$\left(P_i^{n+1} - \frac{s_L}{2}\right)[1 - m(n-i)] + \frac{s_L}{6} \approx P_i^{n+1}[1 - m(n-i)] - \frac{s_L}{12}$$

Adding up the exposures in the triangles, we get total exposures in the square of

$$P_i^n m(n-i-1) + P_i^{n+1}[1 - m(n-i)] + \frac{s_U - s_L}{12}.$$

If the two consecutive cohorts born in years $n-i-1$ and $n-i$ are similar in size, if the mean locations of birthdays in each year for these cohorts are both close to $\frac{1}{2}$, and if migration balances are similar in the two triangles, then the exposures are close to $(P_i^n + P_i^{n+1})/2$ and the constant risk function λ is estimated by

$$\widehat{\lambda} = \frac{SQ_i^n}{\left(P_i^n + P_i^{n+1}\right)/2}$$

where the occurrences SQ_i^n are indicated in Figure 3(b).

On the other hand, if cohorts born years $n-i-1$ and $n-i$ are quite dissimilar in size or if the mean locations of birthdays are quite different in these two cohorts, the latter formula may prove inaccurate. This is the case when a major disruption in the birth rate such as that provoked by the outbreak of a war occurs during the course of either of the 2 years. The consequence is then a multiplicative bias of approximately

$$\frac{B(n-i)\left[\frac{1}{2} - m(n-i)\right] - B(n-i-1)\left[\frac{1}{2} - m(n-i-1)\right]}{[B(n-i) + B(n-i-1)]/2}$$

in the above estimate of λ. Here $B(G)$ denotes the absolute number of births recorded in year G. The bias is approximately a constant percent of λ. For example, rates calculated for Belgian and French cohorts born in 1915 and 1916 are systematically biased upwards by almost 15%. This bias has almost the same magnitude for any kind of event (fertility, nuptiality, or mortality) and for any age. Rumanian cohorts born in 1966 and 1967 show a bias of a similar size caused by the huge increase in births subsequent to a change in the legislation on abortion in October 1966.

To avoid such biases, one should observe demographic events in vertical-sided parallelograms rather than in squares when the age-pyramid shows irregularities due to major historical events. Contrary to common language, 'statistical' age at the time of occurrence is preferably age attained during the calendar year rather than completed age at the occurrence of the event.

Note that if E is a non-repeatable event, the probability of occurrence of E during a 1-year period, given that it has not occurred before the beginning of the period, is $1-e^{-\lambda}$ under the assumption of a constant risk function equal to λ, and if the

Figure 3 (a) Events observed in a vertical-sided parallelogram. (b) Events observed in a square.

observed rate r is small, the probability is estimated by $1-e^{-r} \approx 1/(1+\frac{1}{2}r)$.

The value of $m(G)$ hardly changes over years n for a given cohort G; mortality and migration do not alter substantially the characteristics of the distribution of birthdays of the cohort through time, even when these characteristics are exceptional. These characteristics can then be approximated by their value at the time of birth i.e., on the basis of the monthly distribution of births that occurred during year G. They can also be estimated from census data i.e., on the basis of a breakdown of the resident population by year and month of birth.

More Sophisticated Assumption: Variable Risk Function

In our second step we now turn to more refined approximations. We still assume that the risk function is independent of the time g at birth but we now allow (soft) variations with age x. The risk of occurrence of the event E at an exact age comprised between x and $x+\mathrm{d}x$ among the $N(g)\mathrm{d}g$ residents born between g and $g+\mathrm{d}g$ is $\lambda(x)\mathrm{d}x\mathrm{d}g$. The risk function λ will be assumed to be a quadratic polynomial inside several adjacent regions of the LEXIS diagram in the case of a repeatable event, and a linear polynomial in the case of a non-repeatable event. In the latter case, especially if E is death, we may alternatively assume that it is $\log[\lambda(x)]$ that varies linearly over an interval of a few years of age. This corresponds to the Gompertz law of mortality, which is generally valid at higher ages (say at ages over 30 or 40) below the oldest old. The density s of net entries due to migration (or to deaths if E is not death itself) is still assumed to be constant inside each vertical-sided parallelogram in the LEXIS diagram.

For the following reason we need to estimate the integral of $\lambda(x)$ over a 1-year interval, say between a and $a+1$, where a is either i or $i-\frac{1}{2}$. For repeatable events the mean number of occurrences per person between ages a and $a+1$ is $\int_a^{a+1}\lambda(x)\mathrm{d}x$. For non-repeatable events the probability of recording E between ages a and $a+1$ among those who have not recorded it before age a is $1-\exp(-\int_a^{a+1}\lambda(x)\mathrm{d}x)$. In both cases the integral plays a central role.

If the derivatives λ' and λ'' are not too large (i.e., if λ indeed has 'soft' variations), the integral can be estimated on the basis of available estimates of λ, λ', and λ'' as follows. We get

$$\int_i^{i+1}\lambda(x)\mathrm{d}x \approx \lambda\left(i+\frac{1}{2}\right)+\frac{\lambda''(i+\frac{1}{2})}{24} \approx \lambda(i)+\frac{\lambda''(i)}{2}+\frac{\lambda''(i)}{6},$$

and

$$\int_{i-1/2}^{i+1/2}\lambda(x)\mathrm{d}x \approx \lambda(i)+\frac{\lambda''(i)}{24} \approx \lambda\left(i+\frac{1}{2}\right)-\frac{\lambda'(i+\frac{1}{2})}{2}+\frac{\lambda''(i+\frac{1}{2})}{6}$$

Vertical-Sided Parallelograms

Under the above assumptions, the number of events occurring in the vertical-sided parallelogram for a repeatable event is

$$VSP_i^n = N\left[\lambda+\lambda'\left(m-\frac{1}{2}\right)+\frac{\lambda'}{2}V\left(\frac{1}{3}-m+m^2+V\right)+s\frac{\lambda'}{6}\right]$$

and for a non-repeatable event it is

$$VSP_i^n = N\left[1-e^{-\lambda-\frac{\lambda'}{2}(1-2m)}\right]e^{\lambda m}-\frac{\lambda'}{2}\left(m^2+V\right)+\frac{\lambda^2}{2}V + \frac{s}{2}\left[2-e^{\frac{\lambda}{3}-\frac{\lambda'}{6}+\frac{\lambda^2}{36}}-e^{\frac{\lambda}{3}-\frac{\lambda'}{6}+\frac{\lambda^2}{36}}\right]$$

In these formulae, N is the number of persons who reach their ith birthday during year n. (This is estimated by the mid-value of P_{i-1}^n and P_i^{n+1} in the case of a repeatable event, and by the mid-value of P_{i-1}^n and P_i^{n+1} plus half the difference between the number of occurrences of E in the upper triangle and in the lower triangle of the parallelogram, in the case of a non-repeatable event.) Furthermore, λ, λ', and λ'' are the values of the risk function and of its two first derivatives at exact age i, s is the density of net entries inside the parallelogram, and m and V are the mean and variance of the locations of birthdays in the cohort born in year $n-i$. (If the distribution of birthdays in the cohort is *uniform*, m is equal to $\frac{1}{2}$, V to $\frac{1}{12}$, and the third moment μ is zero. When the actual distribution of birthdays differs from uniformity only due to usual seasonal variations in the number of births, there is no need to take care of non-uniformity because m is then close to $\frac{1}{2}$, and V to $\frac{1}{12}$.)

If we know N, m, and V, and if we estimate λ' and λ'' on the basis of the values of λ at neighboring ages, the appropriate formula above yields an estimate for λ. This is done iteratively and the iteration process is stopped when λ has stabilized for all i. In the first iteration, λ' and λ'' are set equal to zero. In subsequent iterations, $\lambda'(i)$ may be estimated by $\frac{1}{2}[\lambda(i+1)-(i-1)]$ and $\lambda'(i)$ by $\lambda(i+1)+\lambda(i-1)-2\lambda(i)$, where λ values are those obtained in the previous iteration at adjacent ages $i-1$, i, and $i+1$.

Squares

The corresponding equations in the case of squares are for a repeatable event

$$\begin{aligned} SQ_i^n = {} & N_1\left[\lambda m_1+\frac{\lambda'}{2}\left(m_1-m_1^2+V_1\right)\right] \\ & +\frac{\lambda''}{2}\left(\frac{m_1}{4}+\frac{m_1^2+V_1}{2}+\frac{m_1^2}{3}+m_1V_1+\frac{\mu_1}{3}\right) \\ & +N_2\left\{\lambda(1-m_2)-\frac{\lambda'}{2}\left[m_2-m_2^2-V_2\right]\right. \\ & \left.+\frac{\lambda''}{2}\left[\frac{1}{12}-\frac{m_2}{4}+\frac{m_2+V_2}{2}-\frac{m_2^3}{3}-m_2V_2-\frac{\mu_2}{3}\right]\right\} \\ & +\frac{s_2-s_1}{6}\left(\lambda+\frac{\lambda''}{40}\right) \end{aligned}$$

and for a non-repeatable event it is

$$\begin{aligned} SQ_i^n = {} & N_1\left[e^{\lambda m_1+\frac{\lambda'}{2}[m_1(1-m_1)-V_1]+\frac{V_1}{2}\lambda^2}-1\right] \\ & +N_2\left[1-e^{-\lambda(1-m_2)+\frac{\lambda'}{2}[m_2(1-m_2)-V_2]+\frac{\lambda^2}{2}V_2}\right] \\ & +\frac{s_1}{2}\left[1-e^{\frac{\lambda}{3}+\frac{\lambda^2}{36}}\right]+\frac{s_2}{2}\left[1-e^{-\frac{\lambda}{3}+\frac{\lambda^2}{36}}\right] \end{aligned}$$

In the two latter formulae, $_1$ refers to the upper triangle (or to the cohort born in year $n-i-1$), $_2$ to the lower triangle (or to the cohort born during year $n-1$), N_1 is the number of persons reaching their $(i+1)$th birthday during year n, N_2 the number of persons reaching their ith birthday during year n, λ, λ', and λ'' are the risk function and its two first derivatives at exact age $i+\frac{1}{2}$, s_1 and s_2 the densities of net entries inside the parallelogram containing the upper and the lower triangle, respectively, m_1, m_2, V_1, V_2, μ_1, and μ_2 the means, variances, and third centred moments of the locations of birthdays in the cohorts born in years $n-i-1$ and $n-i$, respectively.

If we know N_1, m_1, V_1, μ_1, N_2, m_2, V_2, and μ_2, and estimate λ' and λ'' from the values of λ obtained in the previous iteration at neighboring ages (with λ' and λ'' set equal to zero in the first iteration), it is possible to derive λ from the number of events in the square using the appropriate formula. The iteration process is again stopped when λ has stabilized for all i.

On the basis of the above formulae, it is possible to estimate the integral of λ over a 1-year range (between exact ages i and $i+1$ and also between exact ages $i-\frac{1}{2}$ and $i+\frac{1}{2}$), whatever the LEXIS diagram region in which occurrences were observed (squares, vertical-sided parallelograms, or triangles). This leads to an estimate of the risk regime at all relevant ages during any year of observation. These formulae make it possible to reach international comparability in spite of the diversity of national practices. (Some countries observe events in vertical-sided parallelograms, others in squares.) For countries where the national statistical office has changed from one system to the other, it also becomes possible to compute a complete time-series with comparable terms.

The Special Case of Mortality at Ages 0 and 1

The above formulae hold for fertility, nuptiality, and mortality at any age, except for mortality at age 0 and, to a lesser extent, at age 1. The reason is that the risk function $\lambda(x)$ of mortality decreases very sharply from birth i.e., from exact age 0. This makes the polynomial approximation invalid over the age-interval (0, 1) and even the interval (1, 2). We now provide a solution even for infant mortality.

Let us denote by D_L^0 and D_U^0 (with $D_L^0 + D_U^0 = SQ_0^n$) the numbers of deaths in the lower and the upper triangles of the first square (i.e., between exact ages 0 and 1), D_L^1 and D_U^1 the similar numbers of deaths in the triangles of the second square (i.e., between exact ages 1 and 2), D_L^2 and D_U^2 those in the triangles of the third square (i.e., between exact ages 2 and 3).

Under the assumption that there is no migration inside the first square and that distributions of birthdays within cohorts born in year $n-1$ and year n are identical (in practice: both departing from uniformity only due to 'usual' seasonal variations), the infant mortality rate $IMR^n = 1 - \exp\left(-\int_0^1 \lambda(x)\mathrm{d}x\right)$ can be estimated by

$$IMR^n = 1 - \left(1 - \frac{D_U^0}{P_0^n}\right)\left(1 - \frac{D_L^0}{B^n}\right)$$

where P_0^n is the population of completed age 0 on January 1 of year n and B^n is the number of live births of the corresponding sex during year n. If net migration is not zero inside the first square, we rewrite the preceding formula as

$$IMR^n = 1 - (1-a)(1-b)$$

Two estimates of each term a and b can be provided. The term a refers to the upper triangle. The first estimate assumes that migration during year n within the cohort born in year $n-1$ takes place exclusively on January 1 of year n. The second estimate assumes that migration during year n within the cohort born in year n takes place exclusively on December 31. We then get the following estimates:

$$a_1 = \frac{D_U^0}{P_1^{n+1} + D_U^0 + D_L^1} \text{ and } a_2 = \frac{D_U^0}{P_0^n}$$

The term b refers to the lower triangle, and our first estimate assumes that migration during year n within cohort born during year $n-1$ takes place exclusively immediately after birth. Our second estimate assumes that migration during year n within cohort born in year n takes place exclusively on December 31 This gives

$$b_1 = \frac{D_L^0}{P_1^{n+1} + D_L^0}, \quad b_2 = \frac{D_L^0}{B^n}$$

It follows that a set of lower and upper bounds of IMR^n are

$$1 - [1 - \min(a_1, a_2)][1 - \min(b_1, b_2)]$$

and

$$1 - [1 - \max(a_1, a_2)][1 - \max(b_1, b_2)]$$

If migration balances are small during year n both inside the vertical-sided parallelogram corresponding to the cohort born in year $n-1$ ($s_U = P_1^{n+1} - P_0^n + D_U^0 + D_L^1$) and inside the lower triangle ($s_L = P_0^{n+1} - B^n + D_L^0$), the two bounds are naturally close to each other. For example, the lower and upper bound of the estimated infant mortality rate were 5.30 and 5.36 per 1000 male live births and 4.16 and 4.13 per 1000 female live births, respectively, in France in 1997. For most practical purposes, the differences are negligible in contemporary Europe.

A satisfactory estimate of the infant mortality rate requires that the numbers of deaths are available for triangles in the LEXIS diagram. If the information available is limited to the total number of deaths SQ_0^n inside the first square, a rough estimate of the infant mortality rate is made possible nonetheless via a preliminary estimate of the breakdown of SQ_0^n into D_U^0 and D_L^0. In contemporary Europe, D_L^0 is approximately 90% of SQ_0^n.

The same procedure can be applied to the estimate of the probability of death between exact ages 1 and 2. The lower and upper bounds of that probability are

$$1 - [1 - \min(a_1, a_2)][1 - \min(b_1, b_2)]$$

and

$$1 - [1 - \max(a_1, a_2)][1 - \max(b_1, b_2)]$$

with

$$a_1 = \frac{D_U^1}{P_2^{n+1} + D_U^1 + D_L^2}, \quad a_2 = \frac{D_U^1}{P_1^n}$$

$$b_1 = \frac{D_L^1}{P_1^{n+1} + D_L^1}, \text{ and } b_2 = \frac{D_L^1}{P_0^n - D_U^0}$$

The lower and upper bounds of the probability of death between exact ages 1 and 2 are usually even closer to each other than the two estimates of the infant mortality rate. For example,

the lower and upper bounds were 4.839 and 4.843 per 10 000 male live births and 4.102 and 4.106 per 10 000 female live births, respectively, in France in 1997. In contemporary Europe, the share of the lower triangle in the second square (between exact ages 1 and 2) is only slightly over 0.5 (around 52–55%).

Literature

The LEXIS diagram got its name from the German statistician Wilhelm Lexis, who published a treatise on the subject some 125 years ago (Lexis, 1875). Like so many methodological innovations, the device is really older (Vandeschrick, 2001; Keiding, 2001). Most straightforward computational formulas above have a similar ancestry, but the more sophisticated ones were developed by the author in a series of publications between 1984 and 1999.

Abstract

Estimates and projections for small areas are used extensively in the public and private sectors, and demand for them has been growing. Because of population size and data availability issues, estimates and projections for small areas face methodological challenges not commonly encountered at larger geographical scales. This article defines 'smallness' for estimation and projection purposes, describes the types and sources of data used, discusses the methods for estimating and projecting small area populations, and assesses recent methodological developments, in particular the impact of the geographic information system and spatial techniques.

Population estimates and projections play a critical role in market analysis, facility planning, environmental planning, and the allocation of public and private funds. Estimates and projections for small areas, in particular, are used extensively in the public and private sectors, and demand for them has been growing. Because of population size and data availability issues, estimates and projections for small areas face methodological challenges not commonly encountered at larger geographical scales. While most population estimation and projection techniques can be used at any scale, the focus of this article is on those approaches that are particularly suited for small areas.

The article is organized as follows: After a brief description of what distinguishes population estimates from projections, 'smallness' is defined and put in context. This is followed by a discussion of the data and sources typically used when preparing small area estimates and projections. Next, various types of estimates are defined. The central sections address in more detail the methods used for small area estimation and projection. The article concludes assessing recent methodological developments, in particular the impact of geographic information system (GIS) and spatial techniques.

Estimates, Projections, and Forecasts

Demographers consider information about a past or present population not based on a census or population register an *estimate*, while information about the future is referred to as a *projection* or a *forecast*. The terms projection and forecast are often used interchangeably, but can be differentiated according to the expected likelihood of their outcomes: a projection is a numerical outcome of a particular set of assumptions regarding the future population, whereas a forecast is the projection believed most likely to provide an accurate prediction of the future population (George et al., 2004: 561). In addition to the time dimension, a key distinction between estimates and projections involves the type of data used. Since projections refer to the size of the population at a future point in time, they cannot be based on actual data comprising the components of population change; rather, they must be based on the extension of either current or expected population trends into the future (Raymondo, 1992).

Smallness

Small area demography refers to demographic applications and analyses executed at local and regional scales (Smith and Morrison, 2005). While no universally accepted definition exists for what constitutes a small area for population estimation and projection purposes, it commonly involves administrative units below the national and state level. Examples include counties, cities, municipalities, townships, wards, local government areas, postal areas, school districts, census tracts, and census blocks; these can vary greatly in area and population size, from less than one to thousands of square kilometers, and from a handful of residents (or none) to over a million. Alternatively, a small area can refer to any subpopulation or domain for which direct estimates of adequate precision cannot be produced (Rao, 2003). Subpopulations or domains are subsets of larger populations defined by criteria other than geographic affiliation such as age, sex, income, educational level, and health status. Smallness can thus be understood in terms of size or in terms of data availability (Alho, 2001: 3484).

Small area analyses face a number of unique challenges not commonly encountered at larger geographic scales: (1) the boundaries of small areas often change over time making time-series analyses challenging; (2) many types of data, especially those covering more detailed population characteristics, are not tabulated for smaller areas, necessitating the use of proxy variables; (3) because of a paucity of data, there are often no discernible past patterns of change that can serve as a basis for estimation or projection, which may require the application of model rates based on areas for which data are available but which may not be directly comparable; (4) even when data are available for small areas, they may be less reliable because of smaller sample sizes and greater sampling variability; and (5) location-specific factors such as institutional populations, seasonal populations, facility closings, or changes in zoning have a greater impact on population changes in small areas (Smith and Morrison, 2005; Murdock et al., 2012). Because of

these challenges, population estimates and projections for small areas necessitate different sets of tools than those applied for larger areas such as states and nations.

Data and Sources

Two general categories of data can be distinguished: *direct data* and *indirect* or *symptomatic data* (Bryan, 2004b: 526). The former measure population and population change directly and can be obtained from censuses, administrative records, and surveys. Indirect data provide information indirectly related to, or symptomatic of, the population being estimated or projected; examples include school enrollment, tax returns, vital statistics, employment statistics, voter registration, electrical hook-ups, and housing counts. There is no clear dividing line between the two categories of data; the same data can be direct for one type of estimate and indirect for another. For example, birth and death counts are direct data when used to estimate natural change in a population but indirect data when used in the censal-ratio method (see later) to estimate total population (Swanson and Tayman, 2012: 43). The usefulness of indirect data depends on the extent to which factors other than population size and distribution influence them.

The primary data sources used in small area demography include censuses, administrative records, and surveys (Smith and Morrison, 2005). *Censuses* generally provide accurate and comprehensive data, regular repetition, fine geographic detail, and relative ease of data access; potential downsides include cost, enumeration difficulties, infrequent updates, falling response rates, differential underenumeration, and concerns about disclosure control (Martin, 2006). While censuses are still generally considered the 'gold standard,' in many countries there has been a movement toward greater utilization and application of administrative data sources and sample surveys to provide more timely data.

Administrative records, which are collected by federal, state, and local government agencies for registration, licensing, and program administration purposes, can provide ongoing information on a variety of demographic events and characteristics (Smith and Morrison, 2005). The most important administrative records for small area estimates and projections are vital statistics (especially birth and death data), which tend to be widely available and generally quite accurate, at least in the developed countries, and which form crucial inputs in many estimation and projection models. Other sources of administrative records come from a variety of fields and cover data related to the economy, education, health, social services, safety and security, community resources and participation, housing, and the environment (Coulton, 2008).

A special case of administrative records are *population registers* in which population characteristics are continually recorded. Population registers can be divided into *universal registers*, which attempt to include the entire population, and *partial registers*, which are established for specific administrative purposes and cover only those persons directly affected by the particular program (Bryan, 2004a: 31–35). Universal registers are maintained by the Scandinavian countries, the Netherlands, Japan, and a few other countries; partial registers are more common and include social insurance and welfare, military service, voter, school enrollment, and judicial data. A continuously updated enhanced master area file has been proposed for the United States; it has the potential to deliver timely, cost-effective, and precise population estimates even for small geographical units, but a number of challenges – ranging from confidentiality and privacy, up-front costs, to accuracy and technical issues – must be overcome for the system to become established (Swanson and McKibben, 2010). To be most useful, administrative records and population registers must be accurate and up to date, allow for linking from one source to another via a personal identification number, and be embedded in a supportive legislative framework (Smith and Morrison, 2005).

The third major source of data for small area estimates and projections is *surveys*. While surveys vary, their central features are the use of a fixed design, the collection of data in standardized form from individuals or organizations such as schools or businesses, and the selection of representative samples from known populations (Robson, 2011: 238). Surveys are often employed to collect data on variables not covered in a census or by administrative records. Surveys come from governmental/official statistics, academic/social research, and commercial/advertising/market research (O'Muircheartaigh, 1997: 1–2). Small sample sizes often limit the usefulness of survey estimates for small areas. This can be the case even for surveys designed specifically to provide accurate and timely demographic, social, and economic data on an ongoing basis for large and small areas, such as the American Community Survey in the United States (Swanson and Hough Jr., 2012). To combat the challenges posed by small sizes, small area estimation techniques have been developed that apply indirect estimators which 'borrow strength' by using values of the variable of interest from related areas and/or time periods, thus increasing 'effective' sample sizes (Rao, 2003: 2).

Types of Population Estimates

Population estimates can be divided – based on their time reference and method of derivation – into *intercensal estimates*, which relate to a date between two censuses and take the results of these censuses into account, and *postcensal estimates*, which relate to a date following a census that take that census into account, but not later censuses (Bryan, 2004b: 523). The former can be regarded as interpolations and the latter as extrapolations. Although postcensal estimates are sometimes made with extrapolative techniques, more commonly symptomatic indicators of population change are applied (see later). Estimates can also be made for dates prior to census taking (*precensal*), which are of interest to historical demographers in particular. The estimation methods discussed in the following section are primarily used for making postcensal estimates, which are the most common type of population estimation. Intercensal and precensal estimates can be made with some of these methods but usually require a different approach (Swanson and Tayman, 2012: 331–355). Estimates can further be divided whether they are made for a legally resident *de jure* population or for a physically present *de facto* population. Most population estimates follow a *de jure* definition, and the

methods described later are primarily applicable to them. *De facto* population estimates, which are useful for estimating daytime, visitor, seasonal, homeless, and disaster-impacted populations, for the most part utilize different sets of techniques (Swanson and Tayman, 2012: 313–330).

Methods for Small Area Population Estimates

The type and quality of data available are crucial determining factors when choosing a method for population estimation (Bryan, 2004b: 526). Estimation accuracy, and how different methods account for uncertainty, are important factors to consider; additional criteria include the provision of necessary detail, face validity, plausibility, costs of production, timeliness, and ease of application and explanation (Swanson and Tayman, 2012: 267–302). There are various ways to classify estimation methods for small areas. A recently developed classification scheme by Swanson and Tayman (2012: 106–107) combined earlier approaches and proposed the following categories: extrapolation, ratio, symptomatic, regression, component, sample based, and other methods. It should be noted that although the estimation methods discussed here have varying data requirements and can be applied across different areas, many less-developed countries have underdeveloped statistical systems and are better served by indirect estimation methods which utilize model life tables and model stable populations (Popoff and Judson, 2004). For an overview of data and methods used for at-risk subnational population estimation, see National Research Council (2007).

Extrapolation techniques, which range from simple linear change to complex ARIMA models, rely solely on the pattern of past population changes to estimate postcensal population, and assume that trends in the postcensal period will be similar to historical trends. Simple extrapolation models are most useful for postcensal estimates close to the last census, when resources are limited, and for very small areas or demographic subgroups; complex models allow the construction of probabilistic intervals around the estimates but are more difficult to implement and not necessarily more accurate (Swanson and Tayman, 2012: 115–127). *Ratio extrapolation methods*, such as share-of-growth, shift-share, and constant-share, express the population of a subgroup as a proportion of a larger population. Like simple extrapolation techniques, they have small data requirements and are easy to apply, but share the general shortcomings of extrapolation methods in that they do not account for differences in demographic characteristics or the components of growth, and they ignore potentially relevant information related to postcensal population changes (Swanson and Tayman, 2012: 127–135).

Symptomatic estimation techniques include the housing unit and censal-ratio methods. The *housing unit method* is one of the most widely used techniques for making small area population estimates (Bryan, 2004b: 550). It relies on the assumption that nearly everyone in a population lives in some type of housing structure. The housing unit method calculates the population of an area as equal to the number of occupied housing units (households) times the average number of persons per household plus the number of persons living in group quarters (e.g., prisons, college dormitories, military barracks, nursing homes). The number of households can be estimated using measures of construction activity such as building permits or certificates of occupancy, using utility data such as a residential electric or telephone customers, from property tax records, and from aerial photographs; the average number of persons per household can be taken from the most recent census, extrapolated as a trend from the two most recent censuses, or estimated using postcensal data in combination with data from the last census; and the group quarters population can be obtained either directly from the facilities or from a past census (Smith, 1986). The housing unit method has a long and successful track record, is flexible in terms of data sources, and can be applied at most levels of geography, but it also requires a major commitment of time and resources as well as sound professional judgment to yield accurate estimates (Smith and Cody, 2004). Recent research that models housing unit change for small areas using a density-dependent growth model, as well as approaches that integrate spatial factors derived from remote sensing and GIS datasets, have shown promising results and hint at future refinements to the housing unit method (Baker et al., 2008; Deng et al., 2010).

The *censal-ratio method*, introduced by Bogue (1950) as the 'vital rates method,' is another symptomatic population estimation technique used for small area estimation. It is related to the ratio extrapolation methods, but is based on ratios of symptomatic data to total population rather than proportions of national, state, or regional totals. The technique involves computing the ratio of symptomatic data to total population at the time of the last census, extrapolating the ratio to the estimate date, and dividing the estimated ratio into the value from the symptomatic series for the estimate date (Bryan, 2004b: 546–547). Symptomatic data that can be used in the censal-ratio method include birth and death statistics, school enrollment data, tax returns, number of electric, gas, or water meter accounts, number of building permits issued, bank receipts, motor vehicle registrations, and voter registration rolls. To be useful, accurate and comparable symptomatic data must be available at frequent intervals, including the census date, the annual number of cases should be high in relation to population size, and the ratio should be stable or change in a regular fashion in order to be projected to the estimate date (Bryan, 2004b: 547).

Regression techniques derive population estimates by means of symptomatic indicators of population change. The *ratio-correlation method* introduced by Schmitt and Crosetti (1954) is the most widely used regression technique for population estimation. It involves relating changes in several symptomatic indicators to population changes – expressed in the form of ratios to totals for geographic areas – by a multiple regression equation (Bryan, 2004b: 548). The symptomatic variables that have been used are similar to those discussed earlier for the censal-ratio method. The *apportionment*, *ratio change*, and *additive change methods* frequently used for making small area population estimates in Great Britain can be considered as simplified versions of the ratio-correlation method (Simpson et al., 1997). Regression techniques for population estimation have a firm foundation in statistical inference, which allows for the construction of meaningful measures of uncertainty (Swanson and Beck, 1994). The ratio-correlation method, in particular, has been used, evaluated, and refined

for over half a century, giving it a large measure of quality control and contributing to its widespread use and satisfactory performance (Swanson, 2004). Regression techniques rely for their accuracy on the validity of the assumption that the relationship between the independent and dependent variables observed in the past will persist in the postcensal period; they also require judgment with regard to the reliability and consistency of coverage of the symptomatic indicators. Shortcomings include potential time lags in the availability of the symptomatic indicators; the use of multiple and differing variables, which make decomposition of error and comparability of estimates between areas difficult; and limitations in producing postcensal estimates by age and sex (Bryan, 2004b: 549–550).

Component methods are based on the demographic balancing equation in which the population at the end of the time period (here, the estimate date) is expressed as the population at the beginning of the time period (commonly the most recent census), to which the number of births and in-migrants that occurred over the time period are added, and from which the number of deaths and out-migrants that occurred over the time period are subtracted. All component methods generally employ birth and death data but vary in how migration is estimated. Of the various component methods, the *component method-II* and the *tax returns/administrative records method* developed by the U.S. Census Bureau are widely used (Murdock et al., 1995; Starsinic et al., 1995). The component method-II employs changes in school enrollments to estimate migration, whereas the tax returns/administrative records method uses address changes on federal income tax returns. If migration data of sufficient quality are available, the *cohort-component method* can also be applied. It divides the population at the launch date into age-sex groups (cohorts) and accounts separately for the fertility, mortality, and migration each cohort experiences until the estimate date (Swanson and Tayman, 2012: 195–206). Although useful when estimates by age and sex are required, the cohort-component method is data- and computationally intensive and more commonly applied for population projections than for estimates. Component methods are attractive, because they specifically account for the three components of population change, births, deaths, and migration. Limitations include that they assume the continuation of historical patterns in symptomatic data in measuring migration, that they can be resource-intense and require data which may not be available for all small areas, and that they may not be appropriate for areas with substantial 'special' populations (Bryan, 2004b: 556; Rives et al., 1989: 30–31).

Sample-based methods of population estimation, which include *synthetic methods*, *structure preserving estimation*, the *ranked set samples method*, and *Bayesian methods*, are more commonly employed by statisticians than by demographers (Swanson and Tayman, 2012: 207–218); for an overview and review of small area estimation methods of this kind, see Ghosh and Rao (1994), Pfeffermann (2002), and Rao (2003). Other methods that are sometimes used for creating small area estimates include *structural models*, *economic-demographic models*, *dual system estimation*, *microsimulation models*, *neural networks*, the *grouped answer method*, *social network analysis*, and various methods related to *spatial demography* (Swanson and Tayman, 2012: 219–242). A *local census*, which provides a direct count of small area populations independent of any other data source, can also be used, though it is expensive and accuracy dependent on the response rate achieved (Simpson et al., 1996; Lunn et al., 1998).

In addition to individual techniques of population estimation, one can also estimate the population by the composite method and by combining estimates. The *composite method*, which was developed by Bogue and Duncan (1959), is a 'portfolio' of separate estimation methods that are tailored to particular segments of the population such as age groups (Bryan, 2004b: 550–551). For example, one could apply the censal-ratio method using births to develop an estimate for the population aged 0–4, the component method using school enrollment data for the population aged 5–17, the censal-ratio method using births and deaths for the population aged 18–64, and administrative records using Medicare data for the population aged 65 and older. The estimates for each age group are then summed up to yield an estimate of total population. Many combinations of methods and data are available, though there exists little empirical guidance in terms of which to choose (Siegel, 2002: 416–417). Another approach is to *combine estimates* made with two or more different estimation techniques. In its most simple way, this involves averaging or weighting the estimates directly; alternatively, one can join estimates from sample surveys and estimates based on demographic analysis as independent variables in a regression model. There is evidence suggesting that combining estimates made with different methods, data, and assumptions improves accuracy and reduces bias (Hoque, 2012; Simpson et al., 1998).

In recent years, much research has been devoted to small area population estimation methods that utilize remote sensing and GIS technologies (Wu et al., 2005; Wang and Wu, 2010). Dasymetric mapping – the redistribution of areal enumeration data using ancillary information for the display of statistical surface data – once confined to visualizing population distribution, is also increasingly being used for estimating the population of small areas (Mennis, 2009; Petrov, 2012). These methods are attractive since they are not tied to the administrative boundaries associated with census or survey data and allow population estimates to be made for user-defined areas. They also show potential for areas where census data and administrative records are unavailable, unreliable, or out of date, as is the case in many countries in the developing world (Hardin and Shumway, 2008; Sutton et al., 2001). While promising, there currently exists a disconnect between academic research and the actual adoption and use of remotely sensed technologies for population estimation purposes, with lack of expertise, technical, application, and financial issues preventing more widespread adoption by practitioners (Hoalst-Pullen and Patterson, 2011).

Methods for Small Area Population Projections

Many of the methods used for producing population estimates can also be applied when preparing population projections, and the sources of data and factors to be considered when choosing among methods are similar as well. There are important differences, though, since estimates are concerned with giving an accurate population count for a past or present

date, whereas projections require that assumptions about future population changes be made. Projections involve more uncertainty, and projection methods vary widely in how they attempt to model it. As was the case with estimates, there are various ways to classify projection methods. For small areas, Smith et al. (2013) propose four types: trend extrapolation, cohort-component, structural, and microsimulation models.

Trend extrapolation models determine future population values solely by their historical values; they range in complexity from simple methods such as linear, geometric, and exponential growth to complex polynomial, logistic curve fitting, and ARIMA time-series models. *Ratio methods* – in which the population or population change of a small area is expressed as a proportion of population or population change of a larger area in which the smaller area is located – is another type of extrapolation that is often used (Smith et al., 2013: 185–213). Recent research developments involve the application of ratio methods in combination with GIS techniques to produce small area projections based on grids (Hachadoorian et al., 2011). Trend extrapolation projection models have a number of shortcomings: on the one hand, they do not account for differences in demographic composition or for differences in the components of growth, provide little or no information on the projected demographic characteristics of the population, have no theoretical content, and generally cannot be related to theories of population change. On the other hand, the small data requirements, ease of application and explanation, timeliness, and low cost of simple trend and ratio models make them an attractive option particularly for small areas where data availability and reliability issues may preclude the application of more complex projection models (George et al., 2004: 571). Furthermore, simple trend models often provide reasonably accurate projections for short and even long horizons, and the empirical evidence suggests that more complex and sophisticated models do not offer more accurate projections, at least for total population (Armstrong, 1984; Chi, 2009; Smith, 1997).

Cohort-component models are the most commonly used population projection method. Going back to the work of Cannan (1895), the cohort-component method accounts separately for the three components of population change: births, deaths, and migration. Most models subdivide the population into age and sex groups, and each demographic subgroup is projected separately; further subdivisions by race, ethnicity, or other demographic characteristics are possible. While assumptions about the future need to be made for all three components of population change in a cohort-component model, migration tends to be the most significant, most volatile, and hardest to predict for small areas. Approaches for projecting migration include methods which use only base period migration data, methods which require some additional qualitative or quantitative information, and methods based on quantitative projections of independent variables (Wilson, 2011: 33–36). Cohort-component models vary further in whether they apply gross or net migration data. Gross migration models range from complex migration pool and multiregional models that are primarily useful for larger areas to simpler biregional models that are easier to apply for small areas. Net migration models can follow a top–down or bottom–up approach; a simplified version proposed by Hamilton and Perry (1962) that treats mortality and migration as a single unit is also sometimes used (Smith et al., 2013: 155–183). The cohort-component method is a very popular projection method because it can incorporate many different data sources, assumptions, and application techniques. It is well suited to provide projections of demographic characteristics in addition to projections of total population. However, the method is also very data intensive and relatively expensive to apply, and the potential lack of complete and reliable data can be a serious obstacle when projecting the population for small areas (Smith and Morrison, 2005).

Structural models form the third major group of projection methods. In a structural model, population change is related to changes in one or more explanatory variables, and the focus is generally on modeling migration. There are two major types of structural models: *economic-demographic* and *urban systems models*. Examples of the former include econometric models, models that balance labor supply and demand, models based on population/employment ratios, and regional economic models. Economic-demographic models generally focus on economic variables to project migration, though some include amenities as well; most models are complex, resource intensive, expensive to develop and apply, and primarily used for relatively large areas such as counties, metropolitan areas, states, and nations (Smith et al., 2013: 216–228). For smaller areas, urban systems models are more commonly applied; these typically include land use and transportation characteristics in addition to economic variables and rely heavily on GIS techniques. Like most economic-demographic models, urban systems models tend to be very resource intensive and often require a substantial degree of technical expertise (Smith et al., 2013: 228–237). While not necessarily more accurate than other types of projection methods, structural models are useful in that they can address a wide range of theoretical, planning, and policy questions. They can make important contributions to the planning and decision-making process and are particularly well suited for simulation and scenario purposes (George et al., 2004: 586).

While most population projections for small areas are made with trend extrapolation, cohort-component, or structural methods, a number of additional approaches are worth mentioning. The *housing unit method*, though more commonly applied to prepare population estimates, also shows potential for small area population projections (Foss, 2002). The method takes into account local housing supply and, either explicitly or implicitly, residential land availability, and can also be used to constrain cohort-component projections. It promises to be particularly useful for growing urban areas and areas earmarked for residential development, though projecting its various components is challenging (Wilson, 2011: 20–22). *Microsimulation models* differ from traditional demographic modeling as follows: they use a sample rather than the total population; they work on the level of the individual or the household rather than with grouped data; and they rely on repeated random experiments to derive a projection (van Imhoff and Post, 1998). By modeling individual behavior, spatial microsimulation models avoid aggregation bias, are internally consistent, provide very detailed projection outputs, and allow for scenario and what-if analyses; on the downside, the models tend to be extremely complex, require extensive data and staff resources, and there have been few attempts to

validate the assumptions and outcomes of these models (Birkin and Clarke, 2011; Wilson, 2011: 37–38). Another avenue of recent research involves the incorporation of spatial effects into the projection model. Originating in the geographic concept of spatial diffusion – the spread of a particular phenomenon over space and time – *spatial diffusion* and *spatio-temporal projection models* incorporate population spillovers and legacy effects arising from neighboring growth rates and characteristics into the model (Thrall et al., 2001; Chi and Voss, 2011). While these methods address a major shortcoming of most projection models used for small areas – which treat each unit of geography as an independent, stand-alone entity rather than as an entity surrounded by other areas with which they interact – they have not been found to outperform forecasts made with simple extrapolation methods (Chi and Voss, 2011; Chi et al., 2011).

As was true with estimates, *combining projections* using simple averages, weighted averages, trimmed means, and composite approaches, is another option. Combined projections are ideally derived from methods that differ substantially from one another and that draw from different sources of information; combining has been found to improve forecast accuracy under many conditions (Ahlburg, 1995; Armstrong, 2001, 2006; Clemen, 1989; Rayer, 2008). Finally, in addition to projections of total population and by demographic characteristics, many types of planning, budgeting, and analysis also require projections of households, school enrollment, employment, health, poverty, or other population-related characteristics. While structural models are often applied for these purposes, the *participation-ratio* and *cohort-progression methods* are worthwhile to consider. In the former, socioeconomic characteristics are related to demographic characteristics through the use of ratios; in the latter, projections are developed by 'surviving' people with particular socioeconomic characteristics (George et al., 2004: 586–590).

Among the most important advances in recent years has been the development of *probabilistic projection methods* (Wilson and Rees, 2005). Probabilistic methods acknowledge that forecasting the population entails a significant amount of uncertainty, especially for longer time periods, for places with small or rapidly changing populations, for certain age groups, and for the demographic components of population change. Conventional deterministic projections provide a single population number, or high and low variants that do not attach probability to the high–low ranges. Probabilistic methods, in contrast, assess and communicate uncertainty by providing forecasts that come with probability distributions or that are fully probabilistic, i.e., generated by probabilistic population renewal (Lee, 1998). Predictive intervals are commonly made with three distinct approaches: (1) time-series analyses; (2) expert-based probabilistic projections; and (3) ex-post analysis, i.e., the use of past forecast errors (Bongaarts and Bulatao, 2000: 200–204). Most of the research on probabilistic projection methods has focused on large geographic areas such as nations, states, and regions. Yet a probabilistic approach is arguably even more important for small areas, given the greater uncertainty of future population changes at the subnational level (Tayman, 2011; Wilson and Rees, 2005). Cameron and Poot (2011) discuss some of the challenges of providing probabilistic projections for small areas and offer directions for further methodological development.

From Administrative Units to User-Defined Areas?

In the first edition of this article, Alho (2001: 3484) opined that "with the development of the GIS, small area estimation and forecasting will no longer be limited by administrative boundaries." Arguing that administrative boundaries are frequently not well suited to many types of social and medical research, and that domains of interest may intersect several areas or be too small for their effect to be discernible in small area data, the introduction of GIS techniques was viewed as a major step forward for small area estimation and forecasting (Alho, 2001: 3485–3486). Smith et al. (2001: 365–367) also predicted a bright future for GIS in small area analysis, but argued that while GIS techniques may be particularly useful when combined with remote sensing to develop small area population and housing estimates, for projections the main value of GIS would likely be in developing databases rather than in constructing projections per se. Now, more than a decade later, one can ask: to what extent have small area estimates and projections incorporated spatial techniques, and how much progress has been made to overcome the limitations of estimating and projecting populations based on administrative units?

As discussed earlier, in recent years much research has focused on population estimation using remote sensing and GIS techniques. Not only have these techniques created new and alternative means of acquiring population estimates for small areas previously estimated with traditional methods, they also allow estimates to be made for user-defined areas that were hard to come by in the past. On the other hand, the literature on projections made using GIS techniques remains sparse. Projections require assumptions about the future, and while GIS and spatial techniques can add to our understanding of past changes and present population distributions, they do not make forecasting them easier. It seems likely that for the foreseeable future GIS and spatial techniques will remain most useful as tools for distributing populations projected with established demographic models to areas smaller than, or different from, those they were originally made for, rather than providing an alternative projection approach.

Most small area estimates and projections are still made for administrative units, and a major shift toward user-defined areas is unlikely to happen soon. Most of the required input data are still collected for administrative units, and methods that allow for customized bottom–up aggregations – such as microsimulation models – or methods that transcend administrative boundaries – such as remote sensing and GIS techniques – have not yet replaced estimates and projections made with established demographic models. Administrative units can be inconvenient to work with, but they often represent meaningful entities for which knowledge about past and present population changes exists. While small area population estimates and projections will always contain an element of uncertainty, this professional knowledge, when combined with a careful selection of data and methods, still

provides the best foundation for satisfactory estimation and forecasting outcomes.

Abstract

Demography has developed since the seventeenth century as a core set of analytical techniques for evaluating observed change in population aggregates in relation to the varying processes of mortality, fertility, and migration. It has been dependent on the apparatus of nation-states to generate its essential data of population age- and sex-structures and flows of vital events. Crucial technical developments have been the perfection of life tables and of stable population theory. The necessarily contentious interpretation of the causes of demographic change involves a wide range of ecological, political, and cultural factors, with the seminal work of Thomas Malthus (1766–1834) remaining highly influential.

Demography is the study of processes of change in human populations. Demography consists of three interrelated intellectual activities: the collection and validation of appropriate evidence; analysis using an expanding and sophisticated body of mathematical and statistical techniques, which are designed to avoid a range of pitfalls; and, finally, the interpretation of the relationship between the revealed demographic processes and the encompassing epidemiological, natural, economic, and social environments. To a limited extent these relations can be analyzed quantitatively but interpretation also requires engagement with wider issues relating to culture, religion, ideology, politics, and international relations, as exemplified in the seminal work of the field's most influential founding thinker, Thomas R. Malthus (1766–1834).

The gradual emergence of the modern discipline of demography between the seventeenth and nineteenth centuries was associated with an increasingly exclusive focus on mathematically tractable properties of population aggregates. Foucault has identified this schematically with an increasing focus of sovereign powers – typically nation-states – on their populations as aggregates, which came to be conceived within analytical demography analogous to biological entities of the natural world, with processes of fertility and mortality of paramount concern for explaining change over time. Hence knowledge of the age- and sex- structure of the population has been necessary in order to measure these processes accurately, requiring appropriate official census and registration systems to provide the necessary data. Kreager points out, however, that since at least Aristotle, there has also always been a second approach to the study of human population change, which addresses sociocultural and political questions of what determines mutually acknowledged membership of a defined population, independently of the biological facts of life of birth and death. As Bashford has recently shown, toward the close of the nineteenth century the most economically advanced nation-states became aware of the practical importance of such issues of membership of their national populations as their imperialist aspirations bumped up against each other in a newly 'closed world' lacking any further uncharted and unclaimed open frontiers. Such ecological competition was also informed by increasingly dominant racist and social Darwinist conflated perceptions of the physical and cultural differences between human groups. Attempts to control and guide or prevent certain population movements, to secure desired imperialist patterns of settlement across the globe, became a new object of state policy, with the proliferation of the technology of the international passport *c.*1880–1930, as both symbol of an individual's membership of a national population and tool for attempting to control migration.

As an institutionalized academic discipline, demography is a relatively recent arrival in the social sciences. Before World War II there were only a handful of established academic posts in demography, mostly privately funded in the US universities, a couple at the London School of Economics. Yet, officials performing at least some key population counting and accounting tasks have existed for millennia, by virtue of the obvious importance to political leaders of enumeration of populations, or at least sections of them, for fiscal, military, administrative, and colonial purposes. This dates back to the world's ancient civilizations, for instance, in Mesopotamia, China, and Egypt. Furthermore, compilation of family genealogies and maintenance of vital registers of births, marriages, and deaths both for religious and legal purposes have venerable histories, too; and the data they generated are now proving to be of value for demographic historians of early modern Europe, North and South America, Japan, and China, for instance.

Modern demographic study of population aggregates requires two kinds of information. First, on the current stock of the defined population (numbers of each sex alive at each year of age) usually supplied through accurate and regular census details (now taken decennially in most countries); and second, information on the continuous flow of vital events, the numbers of each sex born alive, and the numbers dying at each exact age. This permits calculation of the age- and sex-specific rates of fertility and mortality necessary for genuinely comparable measures of a population's principal dynamic demographic characteristics. Allowing for the effects of net in- or out-migration requires an additional source of information for accurate demographic measures of fertility and mortality, with various forms of undocumented migration always providing a challenge for demographers to estimate in order to produce unbiased estimates of population change. Many further kinds of demographic and epidemiological analysis can be undertaken provided that the appropriate detailed information is routinely collected, as can occur in advanced

 http://dx.doi.org/10.1016/B978-0-08-097086-8.03031-2

universalist, health care systems, such as details on ages and causes of death, or on mothers' ages and parity (i.e., how many previous live births).

The study of populations of any size presupposes an official apparatus of data collection of some considerable sophistication and demography is therefore unique among the social sciences in the extent of its intimate involvement with the priorities of governments and officials and the wider influences of politics upon the state. Until recently only government bureaucracies could command the clerical resources required for the statistical analysis of national demographic data. Hence demography before 1945 tended to be the preserve of state officials or those with trusted official access. It was in fact government census bureaux, which provided the initial demand for automated punch-card tabulating machines and later for the production of the first nonmilitary electronic computers (the US Census Bureau's UNIVAC, commissioned for the 1950 census). The subsequent proliferation of cheap computing resources has undoubtedly been a necessary precondition for the expansion of demography as an academic discipline with numerous independent, nonofficial practitioners now able to participate in the field of study.

Demography has therefore had a close historical association with the rise of nation-states throughout the entire modern period. But demography's earlier development has also been strongly influenced at times by the needs of smaller, subnational polities, such as the municipalities of Britain since the seventeenth century or the federated states of eighteenth-century Germany. Furthermore, the institutional and intellectual character of demography's rapid disciplinary growth since World War II has been much influenced by explicitly transnational institutions such as the UN and the World Bank and major independent (though mostly American) philanthropic organizations, such as the Rockefeller and the Ford Foundations, which funded the postwar institutional expansion of demography and its associated theory of demographic transition through the UN Population Council and the first centers of training in Latin America, Asia, and Africa. Nevertheless, national governments remain the principal collectors of continuous series of verified, authentic demographic data, so that the nation remains the typical reference 'population' addressed.

Modern demography's origins are conventionally traced to the practitioners of 'political arithmetic' in Restoration England. From the fifteenth century onward, initially among some Italian city states, it was increasingly the practice of European cities to compile bills of mortality – weekly death records – as an early warning system for epidemics, particularly of plague. In London, the existence of this data provided the immediate context for the first recorded efforts at demographic analysis by John Graunt (1629–74), 'the father of modern demography.' In his *Natural and political observations made upon the bills of mortality* (1662), he also used records of London christenings to develop a rudimentary life table. This is the fundamental technique for the correct analysis of mortality because it divides the population into age sections and gives statistics for the probability of dying at each age, which can then be arithmetically summed to a single average life expectancy at any age, enabling populations with vastly different age structures or mortality regimes to be compared. Graunt had thus grasped the two fundamental demographic insights: that the age- and sex- composition of a population powerfully influences the incidence of vital events; and this means that population processes are all significantly interdependent.

Life table techniques developed very gradually over the ensuing century, with notable work by Sir Edmund Halley (1656–1742), the Dutchman Willem Kersseboom (*c.*1690–1771), the German Johann Süssmilch (1707–67), the Frenchman Antoine Deparcieux (1703–68), the Swiss-born Leonhard Euler (1707–83), and a host of British contributors to the so-called 'population controversy' (over whether or not the kingdom's population had increased since the Glorious Revolution of 1688–89, when the civil servant Gregory King had compiled, from tax returns, the only detailed estimate of a European nation's population made in the early modern period). Finally, the first technically correct empirical life table was published in 1815, for commercial actuarial purposes, by Joshua Milne (1776–1851), using accurate census and vital registration data collected for public health purposes in Carlisle by Dr John Heysham (1753–1834) during the years 1779–87.

During the nineteenth century the principal institution promoting the further technical development of demographic analysis was the General Register Office (GRO) in London. This British lead was an unlikely development, in that the British census was not even established on a permanent basis (it had to be invoked by a separate Act of Parliament every 10 years), whereas the Scandinavian countries of Iceland (1703) and Sweden (1749) had already instigated regular census-taking, while the new, expanding federation of the United States of America had also committed itself to regular censuses, as an integral part of its new process of democratic political representation. Meanwhile the French and Belgians, with the Marquis de Condorcet, Pierre-Simon Laplace, Joseph Fourier, Adolphe Quetelet, Alexandre Parent-Duchâtelet, and Louis Réné Villermé, initially led the world in the relevant mathematical fields of probability and the application of statistics to human biomedical affairs. The British lead in 'vital statistics' that opened up in the mid-nineteenth century was due to a chain of chance occurrences. The GRO was created by statute to oversee from 1837, a national civil registration system of births, deaths, and marriages, which was created not for public health or demographic purposes but as a liberal reform granting dissenters, a record of their vital events independent of the long-standing parish registers of the Established Church, in order to ensure nonconformists' legal rights in common with the rest of the population in relation to records for property-holding and inheritance. In 1840, as a temporary expedient this small department of government, the GRO, then became vested with responsibility for taking the nation's fifth census of 1841 (the first occurred in 1801). The Registrar General's recently appointed statistical assistant, William Farr, was an unknown man of humble origins, a trained medical doctor, and a self-taught statistician (partly through a visit to Paris, in 1830s – a leading center of application of statistics to medicine).

A representative member of the European-wide generation enthused by the promise of a statistical science of society inspired by the Belgian astronomer, Adolphe Quetelet (1796–1874), William Farr (1807–83) seized the opportunity presented by his responsibility for processing the two essential

sources required for demographic analysis. He launched a four-decade long career of innovative demographic and comparative epidemiological work. Britain was at this time in the throes of a profound mortality crisis in its industrial cities and Farr saw his work analyzing the death rates as guiding a national public health campaign to reduce 'preventable' mortality from the many infectious and sanitary diseases, which his studies demonstrated to be so variable in their incidence in different local government jurisdictions across the land. Of course rural Ireland also suffered the calamity of its great famine in the late 1840s but Farr's remit did not extend there. Although Ireland was an integral part of the United Kingdom from 1801, there was to be no vital registration system for the property-less, Catholic peasantry until 1864. Thus, while it was in a Parisian publication that the term 'demography' was first coined in 1855 – by Quetelet's Belgian countryman, Achille Guillard – it was in Britain that it was most intensively practiced and developed as 'vital statistics.' Significant work was certainly also done in other official statistical offices. Indeed, the most important subsequent innovation following the perfection of the life table in the development of demographic techniques of analysis was the Lexis diagram invented by the German statistician, Wilhelm Lexis (1837–1914), in 1875 for representing the relationship between cohorts (or generations) and period effects (events).

The GRO's lead was surprising in another sense in that the single English name most widely associated with the origins of demography is not the civil servant William Farr with his primary medical focus on preventable mortality, but the cleric and academic, Thomas Robert Malthus, whose focus was on the economy and preventable fertility. Malthus's *An essay on the principle of population, as it affects the future improvement of society*, published anonymously in 1798, famously enunciated on page 14 of its opening chapter that "Population, when unchecked, increases in a geometrical ratio. Subsistence increases only in an arithmetical ratio." He argued that all policy to enhance a population's welfare was conservatively constrained by this limitation principle. Malthus, who held the first ever Chair in Political Economy in Britain and regarded Adam Smith as his principal mentor, thereby applied the fundamental economic problem of scarcity to demography and produced an ecological analysis, which, as is well-known, subsequently independently stimulated first Darwin and then A.R. Wallace to each apply a similar logic to the problem of the origin of species, thereby coauthoring in 1858 the theory of evolution through survival of the fittest.

Malthus was therefore, at once, a seminal influence on evolution, ecology, and demography. In relation to demography this was especially in terms of the third intellectual activity outlined above, interpretation. His forthright axioms and their policy implications demanded a response from the intellectuals of every country and secured a permanent place for the discussion of population problems in the social and biological sciences and in the corridors of government and power. In the five-times revised and extended editions of his *Essay* in his own lifetime he continued to feed the debate, further analyzing and exploring the manner in which aggregate population change, mortality and migration, and individuals' and families' reproductive behavior is integrated into the encompassing natural, social, and economic environment, while utilizing an ever-increasing range of examples drawn from across the world to show how profoundly they were also influenced by customs, beliefs, and politics. He notoriously drew the wrath of Marx for his support for the radical reduction of the nation's welfare net which resulted in the amendment of the Poor Laws in 1834, on the grounds that its 'generosity' was discouraging prudence among the prolific poor who married too young and so had too many children. However, as Bashford points out, Malthus cannot be caricatured simply as a heartless apologist for bourgeois capitalism and European expansion – his moral concerns for the future of the indigenous inhabitants of North America and their way of life contrast interestingly with the contemporary views of Benjamin Franklin, for instance. While Mao Zedong's initial policy for Communist China, 'more people, more power,' was, following Marx, consciously anti-Malthusian, China retained allegiance to communism when it radically reversed this policy with the hyper-Malthusianism of the one-child policy from the late 1970s under the influence of the 'Song group' of technocrats, whose rise to policy preeminence has been documented by Greenhalgh.

Throughout the remainder of the nineteenth century, however, most of those studying demographic phenomena were, like Darwin, gentlemen scholars in local and national statistical societies; also medical men, municipal, and some state officials scattered all across Europe and North America. From mid-nineteenth century they met periodically at International Congresses of Statistics, then of 'Hygiene and Demography' and eventually of 'Eugenics.' But it was not until the interwar decades of the twentieth century that demography began to emerge with an independent disciplinary and professional identity, marked initially by the formation in 1928 of the International Union for the Scientific Study of Population, followed in 1931 by the foundation of the Population Association of America.

However, this formative era from the late nineteenth century onward had also witnessed the rise of nationalist and imperialist rivalries and associated racist, social Darwinist ideologies. This came to exert a dominant (though not uncontested) influence over the practice of demography during the interwar years. French demography was perhaps the first to experience this overtly nationalist and xenophobic current, in the form of a defensive pronatalist popular reaction to defeat in the Franco–Prussian war of 1870–71. This was partly ascribed to her extremely low birth rate, the French being the first nation in the world to have practiced widespread family limitation. The titles of the works of France's leading demographers, such as Arsène Dumont, Jacques Bertillon, and Adolphe Landry repeatedly referred to 'Dépopulation' and 'decadence' while her great novelist, Zola, writing in exile in London after the Dreyfus affair, mourned France's lost *Fécondité* (1899). The study of population problems in the interwar period became increasingly subsumed within this social Darwinist agenda. With its continuing necessary association with the state, demography was inevitably heavily implicated in the policies of the Fascist and Nazi regimes with their totalitarian ideologies. Under the Nazi regime the potential for both demographic and economic forms of analysis to be applied as analytic systems of logic devoid of humane or moral considerations became tragically manifest. Nazi Bevölkerungswissenschaft mechanically

extended the notion of an economically optimal density of population (relative to capital and living standards, rather than simply land), which had underpinned Hitler's racist notion of Lebensraum, to arrive at apparently logical but murderous conclusions that population densities should be reduced in inefficient circumstances, where Jews and Poles were concerned, for instance.

International demography conferences in both Rome and Berlin in the late 1930s were partially boycotted and disrupted due to concern at the emerging demographic policies of Fascist regimes. But even in more liberal Britain, USA, or social democratic Sweden, demographic analysis became obsessed with class-differential fertility, 'problem families,' and fears of a 'flight from parenthood' associated with a succession of illiberal movements for national efficiency, eugenics, and 'social hygiene.' Only in the ideologically separatist USSR, was population analysis relatively free from this association (until Stalin's own pronatalist drive during the war). But this was primarily because of the absence of Western-style demographers, due to Marx's historic demonization of Malthus as the ultimate apologist of the bourgeoisie and their 'dismal science' of political economy. In the massive, unmanageable continental empire of the new Soviet Union, Hirsch shows how the alternative (Aristotelian) 'compositional' and membership approach to population accounting was dominant in the official practice of the revolutionary people's commissars: a preoccupation with mapping the geographical distribution of ethnic nationals (*narodnosti*) and with the control of movement of categories of workers in the economy through the use of an internal passport system in fact inherited from the Tsarist regime, the Propiska, similarly to the Chinese Communist state's subsequent adapted usage of the ancient Hukuo system of household registration.

In the non-Communist world in the immediate aftermath of World War II and Nazi excesses, in Europe, it was only in France and Britain that institutions for demographic research positively flourished. L'Institut National d'Études Démographiques under Alfred Sauvy (1898–1990) and the Population Investigation Committee of the London School of Economics under David Glass (1911–78) both founded their respective journals in 1946, *Population* and *Population Studies*, respectively. However, the decade of the 1940s in fact marks a significant shift in which the center of gravity of the discipline of demography migrated from the colonial powers of Europe to USA. It was symbolic of this coming change that in work published between 1907 and 1939 a European-born but American-naturalized mathematician, Alfred Lotka (1880–1949), devised the proofs for the equations of renewal processes, which underlie stable population theory (showing that populations always come to exhibit a constant age structure and growth rate if their fertility and mortality rates are unchanging). This has proved to be the most important mathematical advance in demography since the perfection of the life table technique (which applied to nonrenewal processes). Intriguingly, unknown to Lotka, Leonhard Euler (1707–83) had already solved these equations in the eighteenth century. Indeed, Lotka's work itself remained largely unexploited until after World War II, both facts which demonstrate that technical advances within social science disciplines do not in themselves necessarily cause change but are dependent on the institutional context and on 'demand' factors external to the discipline.

After World War II, demography rapidly responded to the 'demand' of the growing global preoccupation with planned economic growth, propelled in this direction by the US strategic interests in the context of the Cold War rivalry with the USSR for client states among the many decolonizing peoples of the less-developed world. Consequently, the period since 1945 has become a relatively clearly demarcated third era in the history of demography when, with racist sociobiology discredited, in many senses it returned to the original Malthusian economic agenda and a policy preoccupation with fertility restraint, especially in the 'developing' countries where most of the world's poor reside. The model of 'demographic transition' has dominated the discipline's approach throughout this era. This is a general historical model, promoted and adapted by Frank Notestein (1902–83), the highly influential and well-connected first Director, 1936–59, of the Princeton Office of Population Research (OPR), the most important institutional center for the new American-led demography. Demographic transition 'theory' proposes that in order for a nation to achieve sustained long-term economic growth it must reduce both its mortality and, especially, its fertility levels to those attained by the 'modernized,' liberal democratic Western countries. The model has surprisingly little consistent support in either the historical or contemporary record but it has survived repeated revisionist challenges and has undoubtedly served the discipline well as a model that is compliant with an overarching ideological position endorsing the goals of promoting economic development of liberal market economies round the world. This has successfully elicited a continuous flow of funds for both research and family planning programs from Western governments and philanthropic foundations.

It was in this policy context that external demands increased for various applications of stable population theory. Within the dominant postwar liberal consensus of 'modernization theory,' economic growth was seen as a generic process, such that less-developed countries could be engineered to repeat the experience of the developed countries. Fertility restraint and mortality reduction were important population policy inputs to permit the occurrence of incremental capital–output ratios, considered essential for industrialization. This would be jeopardized by too great a demographic dependency burden (too many young and invalid old in the population) diverting national income into current consumption instead of savings and capital accumulation. Stable population theory enabled model life tables to be devised by A.J. Coale (1917–2002) (Notestein's successor as Director of OPR) and Paul Demeny, and indirect estimation techniques to be formulated by W. Brass (1921–99) of the London School of Hygiene, which permitted the measurement of demographic parameters in many of the less-developed countries where primary information, both census and, especially, vital registration, was defective. A further application, for the same reason, has been its use in back projection and generalized inverse projection in historical demographic work. Along with the application of ground-breaking work in the 'family reconstitution' of historical communities by Louis Henry (1911–91), this has enabled Sir E.A. Wrigley (b.1931) and his colleagues at the Cambridge Group for the History of Population and Social Structure to utilize the parish registers of

baptisms, marriages, and burials originally established by the Tudor monarchy to reconstruct the detailed demographic record of the first industrial nation, England, back to the mid-sixteenth century, thereby, incidentally, demonstrating the invalidity of the demographic transition model in this important case.

Demography has achieved a considerable degree of disciplinary and institutional success, in many senses enviable by the standards of the other social sciences. Since 1945, training institutions have proliferated, primarily under the aegis of the Rockefeller-funded Population Council located in New York, so that demographers are now trained in many centers in all the continents. By plausibly reducing, for certain purposes, the complexity of human affairs in matters of reproduction, morbidity, mortality, migration, and mobility, to tractable mathematical models, demography has achieved considerable analytical power. Like classical and neoclassical economics, conventional demographic analysis embraces a positivist epistemology. It also starts from the liberal and 'democratic' foundational fiction that each individual can, in principle, be legitimately treated as an equivalent accounting unit, a presumption that could only make sense in a post-Lockean world, where a working man could be deemed to count for the same as a prince, hence demography's first text by John Graunt came from the hand of an exact contemporary of John Locke's, another survivor of the modern world's first overthrow of a supposedly divinely appointed sovereign. The resulting accounting system has provided the basis for an increasingly elaborate range of useful technical developments, such as, recently, multistate and multiregional demography.

Inevitably, however, there is an intellectual price to be paid for the preservation of demography's analytical rigor. Rather like the practice of so-called 'mainstream economics,' this, along with its close relationship with the policy needs of governments and other agencies involved in planning and development practices, has tended to insulate demography somewhat from the discipline of full engagement with the rest of the social sciences and humanities. Like all scientific activities, demography socially and ideologically constructs its objects of study but there has been little explicit acknowledgment of the implications of this. Thus, for a discipline, which has devoted much energy to refining, for instance, calibration of the proximate (biological and physiological) causes of fertility variation, there has been much less interest in understanding how the demographers' own concept of fertility itself has arisen, and this applies to other social categories and their context dependence, such as 'population,' 'family,' or 'household.' This disinclination to engage in critical reflexive practice has undoubtedly had significant and, for such an applied and policy-oriented discipline, real consequences. For many decades, vast resources have been devoted to 'family planning' programs aiming to transplant 'modern,' 'Western' contraceptive practices into an enormous variety of diverse cultures. More policy effectiveness might have been forthcoming if both fertility and birth control had from the start been approached as culturally variable entities, whose meanings had to be researched in any population before attempting to modify them.

The future of demography, established as it now is in all the world's major cultures and with departments of practitioners in most governments, is likely to include much more active discussion of the relationship between its inherited inventory of 'Western' social categories and those of other peoples, something also likely to follow from the increasing sophistication of historical and anthropological demography. It is likely to be less exclusively consumed with the problems of engendering economic growth and more with social equity and public health issues, including those of longevity and 'aging,' along with – another Malthusian inheritance – ecological problems of the uses and distribution of material wealth, plus the major issues of the rise of international migration and mobility in a more culturally interconnected ('globalized') but also more unequal world economy. This would, to some extent, represent a return, on a global scale, to the issues, which so preoccupied the mid-nineteenth century demographic observers of the human disruption wreaked in Britain and Europe by the world's first great wave of rapid economic growth. At the same time greater reintegration of demography into the intellectual concerns of both the biosciences and also the wider humanities is likely to be mutually beneficial, with the recent advances in study of the human genome, greater appreciation of gender and sexual diversity, and also of the changing planetary environment as three salient and diverse examples of major recent intellectual developments likely to impact on the ways demography is used and studied in the future.

Abstract

For an intellectual activity to become a discipline, certain things are needed: a significant interaction among those performing the activity; an organization that directs its investigation and teaching; and entities outside itself who value and use its findings. Using this definition, demography lacked the status of a discipline for the first half of the twentieth century. It became a discipline in the second half of the twentieth century largely as a result of a confluence of events that took place at mid-century, the most notable of which was the rise of an international population control movement that expanded vastly the resources available for demographic research on problems associated with population growth in developing countries. These resources helped to establish demography within the academy and to shape its contours, but also worked to politicize the discipline for several decades. Currently, demography possesses a disciplinary cohesiveness that arises from its well-defined subject matter and methodology, and from a common set of policy concerns. Certain twenty-first century trends, however, are likely to erode that cohesiveness.

Achille Guillard first used the word 'demography' in 1855 to describe a new science of population dynamics, by which he meant the statistical study of the size, condition, and movement of populations. Malthus, a half century earlier, had initiated a period of speculation on population growth's constraining effect on prosperity, but only by mid-century had the collection of population statistics become extensive enough in Europe and the United States for a 'science' of population to be imagined. The rise of industrial capitalism in Europe and its overseas extensions increased the pace of social, demographic, and economic change, stimulated the development of state structures aimed at directing these changes, and made obvious the usefulness of accurate population statistics. As India's first census in 1868 reflects, such usefulness extended to the administration of colonies as well. In 1882 the fourth International Conference on Hygiene (Geneva) included a section on demography. By its next meeting in 1884 (The Hague) the conference included demography in its title and sections on "the science of statistics applied to the social well-being of people" were presented. Although the growing body of population statistics was being discussed at international meetings, as the nineteenth century came to an end a unified discipline of demography, with a distinct body of theory and method, had yet to emerge.

Shils notes that for an intellectual activity to become a discipline, certain things are needed: a significant interaction among those performing the activity; an organization that directs its investigation and teaching; and entities outside itself who value and use its findings. Using this definition, demography lacked the status of a discipline for much of the twentieth century. The century began with a diverse group of individuals considering themselves population specialists: statisticians, public health officials, biologists, economists, sociologists, geographers, historians, lawyers, political activists, and politicians. There was haphazard interaction among this group and the teaching of demography had yet to find a clear place within the academy. While basic population statistics had an undeniable utility for those engaged in pragmatic planning activities, there had yet to develop a consensus about the larger significance of modern population changes. In fact, while consensus was developing about the causes of modern population changes, the twentieth century began with growing dissension about their societal consequences. Those engaged in examining population trends warned of very different population problems and recommended conflicting population policies. With such disparate voices speaking about population, a harmonizing core discipline was difficult to detect. The lack of a unifying theoretical perspective that explicated why population mattered, and the presence of a fractured population policy agenda were two factors that obstructed the development of a distinct discipline of demography; these factors continued to inhibit disciplinary development throughout much of the twentieth century.

During the nineteenth century, social movements aimed at influencing population trends arose that attempted to provide the unifying theoretical perspective and clear policy agenda for the study of population statistics. Neo-Malthusianism, based on the belief that growing populations are a major cause of poverty and that lowering fertility by making contraception more accessible will facilitate prosperity, originated in Great Britain early in the nineteenth century and spread gradually throughout Europe. The British Malthusian League was established in 1877, followed by neo-Malthusian leagues in Holland (1885), Germany (1889), and France (1895). But by the time the leagues united at the first International Neo-Malthusian Conference (Paris) in 1900, fertility decline had so spread among urbanizing and industrializing societies that the crisis aura surrounding population growth and large families largely had abated. For countries like France, which were beginning to face the specter of depopulation in the context of an increasingly quarrelsome Europe, it had become less clear that population growth was a social evil or that small families were a social good.

The fertility decline experienced in more developed societies generated new population movements as the twentieth century began. The upper and middle classes were embracing the small family norm more quickly and more fully than other classes. The rediscovery of Mendel's research and the power of

Weismann's work on an inviolable germ plasm had convinced many that heredity played a transcendent role in molding human destiny. The educated of the period were much inclined to use social class position as a surrogate measure of biological quality, and they bemoaned the 'race degradation' that resulted from the 'less fit' lower classes contributing an increasing proportion of future generations.

As early as 1891 Sir Francis Galton, addressing the demography section of the International Conference on Hygiene and Demography in London, was urging that the issue of heredity and fertility be dealt with in the 'practical politics' of member states. As the twentieth century began, eugenics movements were forming in a number of countries. In the United States an active immigration restriction movement allied itself with those expressing eugenic fears. Restrictionists railed against the flood of 'inferior' Eastern and Southern European immigrants who were 'degrading' the high quality of the largely Anglo-Saxon and Northern European 'stock'; they even claimed that the increased number of the 'inferior' was a major cause of fertility decline among the 'superior.'

The eugenists and restrictionists feared changes in population composition and quality, not population quantity and growth. The trend that neo-Malthusians praised, fertility decline, was the same one that they bemoaned. Most eugenists fought to keep access to contraceptives restricted, contending that only the 'more fit' higher classes were sufficiently disciplined to limit their family size. Into this amalgam of population movements Emma Goldman, Margaret Sanger, and Marie Stopes attempted to add 'birth control' movements in the United States and Great Britain. During a period when high-ranking politicians were reminding educated women publicly of their patriotic duty to marry and have children, they began mobilizing citizens to legalize a woman's access to contraception.

With most academic population experts at the time producing works that fed the eugenic-based fears of elites, the task of birth controllers was to develop convincing counterarguments as to why legalizing contraception was socially beneficial. The socialist arguments that Emma Goldman presented – that working-class women could improve their class' negotiating position with capitalists by restricting the production of new workers – had limited public appeal.

Margaret Sanger attempted to attract the allegiance of experts and a wider public by deftly weaving together eugenic and neo-Malthusian themes: restrictive laws do not keep contraception out of the hands of the educated classes and only serve to slow the adoption of birth control among the less motivated 'inferior' classes, an adoption that would benefit both the individual and the society. When during the 1920s the pace of fertility decline increased in developed societies, fears of actual depopulation began to grow and additional controversy swirled around population trends.

Many consider demography a discipline that is either defined by its specialized techniques or delimited by its particular area of study: the causes and consequences of population change, especially the mortality and fertility transitions that have so dramatically swept the world since the 1750s. But for the first third of this century, for a variety of reasons, those engaged in both areas of research found themselves enmeshed in population controversies that made them less able to focus their energies on disciplinary development. For instance, when Louis Dublin and Alfred Lotka developed 'intrinsic' vital rates in 1925 that controlled for the age structure's influence on crude birth and death rates, they applied their technique to the study of US vital rates and dramatically announced that the average American woman in 1920 was having only half a child more than was needed to maintain a stationary population. Dublin then was moved to write articles identifying excessive birth control as a national problem and attacking Margaret Sanger for fostering a one-sided socially harmful movement to lower fertility. In the late 1920s, the technical demographer was hard to distinguish from the movement advocate.

Similarly, experts studying the causes and consequences of modern population movements found the 1930s to be an era in which nationalistic chauvinism made discussion of these trends fraught with controversy. The International Union for the Scientific Investigation of Population Problems was launched in 1928, an outgrowth of the 1927 World Population Conference sponsored by Margaret Sanger in Geneva. The IUSIPP (later to become the IUSSP) planned to hold its first meeting in Rome in 1931. Mussolini's rise to power and hints that the meeting would be used to promulgate his racial theories caused the leadership of the IUSIPP to 'disestablish' the Rome meeting and convene a hastily planned counter-conference in London. The IUSIPP's next official meeting was held in Berlin in 1935, and was even more controversial. Several national committees, correctly fearing that the conference would be used as a platform from which to spread Nazi racial theories, boycotted the meeting. The first two IUSIPP meetings were exercises in divisiveness, and certainly not venues for establishing a new discipline.

Even the academic study of the causes of modern population dynamics proved controversial during the interwar period. By the early 1930s a number of students of population (Warren Thompson in the United States, Adolphe Landry in France, and A.M. Carr-Saunders in Great Britain) arrived at a quite similar summation of modern population dynamics: as agrarian societies become industrial there is a shift from high to low vital rates during which mortality declines more quickly than fertility, producing a period of population growth. Northern and Western Europe and the United States had largely experienced this 'demographic revolution' (Landry's term), Eastern and Southern Europe and Japan were in the middle of their expansion stage, and much of the rest of the world had just begun the revolution.

Although demographic transition theory was to play a central role in the institutionalization of demography 20 years later, its development in the 1930s proved awkward. Both Germany and Japan were using *Lebensraum* rationales for their imperialist moves into their neighbors' land, claiming that their growing populations needed room to expand. Any summation of modern population dynamics that seemed to confer scientific legitimacy on these claims lost attractiveness to a number of Western policy makers. Explicating the causes of modern population changes during this era did little to establish a firm foundation on which to build a disciplinary infrastructure for demography.

The end of World War II, however, began a most propitious period for establishing such a foundation. War-torn nations, both allied and axis, entered into a period of state-planned

national reconstruction. The production and analysis of population statistics were vital for such planning. The National Institute of Demographic Studies (INED) was established in France in 1947 as a planning arm of the Ministry of Social Affairs and National Solidarity. Although not engaged in the teaching of demography, INED did much to enhance the reputation of the discipline, as did the publication of the first volume of *Population* (Paris) in 1946. One year later *Population Studies* made its debut in London. The establishment of two scholarly journals that focused exclusively on publishing analyses with a distinct demographic focus did much to solidify the boundaries of demography as an academic subject. On a more fundamental level, the Population Division of the UN Secretariat was established in 1946 and worked to standardize demographic measures and promulgate a common set of techniques for demographic analysis.

The war's conclusion also resolved many of the more fractious issues that had fueled earlier population controversies, and the link between population discourse and divisive controversy weakened considerably. Knowledge of the enormity of the holocaust led to the eugenics movement dissipating. A widespread postwar baby boom dispelled many countries' worries of depopulation. The removal of German and Japanese military threats broke the association between transition accounts of modern population dynamics and population-pressure rationales for imperialism. In fact, in the postwar world the transition framework would provide Western policy makers with a needed policy tool: a way of interpreting the unprecedented demographic changes arising in the world's underdeveloped regions during the 1950s and 1960s.

The rapid decolonization of the world that followed World War II produced a 'Third World' of newly independent governments that became a Cold War battleground where the United States and the Soviet Union fought for supremacy. Unprecedented mortality decline resulting from the use of newly developed antibiotics and the application of effective methods for combating malaria produced rapid population growth throughout much of the developing world. Such growth was especially problematic when considered from the perspective of the postwar versions of demographic transition theory promulgated by US demographers working at Princeton University's Office of Population. If the economic strains associated with rapid population growth prevented the transformation of traditional agrarian societies into modern industrial ones, then rapid population growth might forestall the very socioeconomic changes that would induce fertility decline. Without fertility decline, the Third World's period of population expansion would come to an end with mortality rising as starvation and disease increased. Starvation, economic stagnation, and growing poverty were judged propitious for the spread of communism. Inducing fertility decline in still agrarian societies came to be seen as the only way to humanely resolve the Third World's population dilemma and, additionally, it would protect the geopolitical interests of the Free World.

This vision of the postwar global population situation was promulgated by Princeton demographers during the decade from 1945 to 1955, especially by Frank W. Notestein and Kingsley Davis. During the early 1950s, John D. Rockefeller III and the leadership of the Ford and Rockefeller foundations accepted the validity of this vision and worked to establish a neo-Malthusian movement with a global focus. Their goal was to set up family planning programs throughout the Third World, lower fertility, and lessen population growth. They recognized that only governments could implement effective family planning programs, and their immediate task became converting government leaders, in both developed and Third World countries, to the position that high fertility was a major social problem in need of state intervention. They determined that a dramatic increase in academic research on international population issues was a necessary first step in this conversion process. During the next two decades they expended millions of dollars to develop demographic research centers that focused on international population issues.

These expenditures on demographic research had a profound impact. In the United States in 1950, for example, courses in demography could be found at the graduate level in only three universities. Between 1951 and 1967 major population research centers were established at 16 US universities; all owed their existence to foundation funding, largely from the Ford Foundation. Similar expenditures helped to establish internationally oriented population centers at a number of major universities in Europe and Australia. Funding from the Population Council, a foundation established by John D. Rockefeller III in 1952 to provide a leadership role for the international population control movement, established UN regional centers for demographic training and research in Bombay, India (1957), Santiago, Chile (1958), and Cairo, Egypt (1963).

Additionally, its fellowship program brought hundreds of Third World students to major population research centers in developed countries for graduate training in demography. The research generated by the rapidly expanding number of demographers found its way into print in the many demographic and family planning journals that foundation funds were instrumental in launching: *Studies in Family Planning* (1963), *Demography* (1964), *Family Planning Perspectives* (1969), *Population and Development Review* (1975), and *International Family Planning Perspectives* (1975). This conscious cultivation of demographers engaged in addressing Third World population issues had the desired effect. While no government leader thought that lowering the fertility of couples was a legitimate state function in 1950, a substantial number did so 20 years later. As governments adopted fertility control policies and implemented family planning programs, additional funds for demographic research became available, as did additional employment opportunities for the alumni of population research centers.

The vast expansion in resources made available for demographic research by leaders of the international population control movement from 1950 to 1975 was largely responsible for establishing demography as an academic discipline worldwide. All the prerequisites for an intellectual activity becoming a discipline – a significant interaction among those performing the activity, an organization that directs its investigation and teaching, and entities outside itself that value and use its findings – were deliberately assembled by this leadership. The decision to fund graduate-level demographic training programs at leading Western research universities assured that there

would be a significant and continuing interaction among those engaged in demographic research. It also assured that academic programs in demography would be established and that standards for the teaching of the discipline would be developed. The many private and government contracts for fertility control research generated a demand for this new discipline's findings by outside entities, a demand that no doubt impressed university administrators.

These resource flows, however, did not simply impact the disciplinary development of demography in positive ways. There were costs as well. The neo-Malthusian impetus behind the institutionalization of demography caused the discipline itself to be tinged with an ideological aura. During the 1950s and 1960s, Soviet and Chinese population specialists constantly questioned the objectivity of Western analyses of Third World population issues. The major premise of the international population control movement was that rapid population growth had deleterious effects on development, and this was certainly the premise that guided the vast bulk of orthodox demographic research. It was, however, more hypothesis than fact. Although it is not uncommon among the social sciences to have certain perspectives represented within a discipline that are based on premises not subject to empirical verification, the discipline itself is usually composed of a multiplicity of such perspectives. Except in France, where a pronatalist tradition among French demographers made many suspicious of neo-Malthusianism, significant counter-perspectives did not develop within Western demography until a stream of 'revisionist' literature began to develop in the late 1970s. Until that lively debate over the actual relationship between population growth and economic development developed, demography's close association with the international population control movement worked to politicize it. At occasions, such as the World Population Conference at Bucharest in 1974, demographers found not only the validity of their research findings questioned but also their motives.

The neo-Malthusian impetus for much foundation and government funding of demographic research also made it subject to the shifting fortunes of that movement. Population research centers were established on the basis of grants with time limits and which lacked departmental status. Many of their positions were 'soft money' nontenured ones, although all had core faculty with permanent positions in established departments, usually sociology, economics, or public health. During the 1950s and 1960s few universities were willing to subsidize population research centers internally, and the survival of demographic training programs required the continual influx of outside funds. Foundation support for the international population control movement remained strong during the 1950s and 1960s but declined dramatically during the 1970s.

The end of the Cold War dissipated a powerful source of Northern concern over problems associated with Southern population growth. Northern government support of the movement was still significant but tended to ebb and flow with shifts in domestic political currents. Academic demography responded to these funding uncertainties by becoming leaner, more embedded within the university framework, and less oriented to an international fertility control agenda. In the North, where the discipline still finds its center, every country faced a significant aging of its population and many faced problems associated with long term below replacement fertility. These domestic population concerns increasingly became the disciplinary focus of Northern demographers and population research centers. A similar transformation occurred in many Southern countries where fertility was falling to replacement levels and below. Only in countries with still high fertility levels did demographic research remain synonymous with fertility reduction research. The one population trend that attracted the attention of demographers in all regions was international migration. A globalizing economy accompanied by great disparities in national wealth was causing a persistent mass movement from the South to the North.

As the twenty-first century commenced, the most notable development in the field of population was that a discipline of demography much like that envisioned by Achille Guillard in 1855 finally arrived. The study of the causes and consequences of population dynamics had become a widely recognized intellectual activity that was investigated and taught within an academic setting by individuals with academic credentials who were paid for their specialized knowledge and who reproduced themselves by producing a new generation of demographers. The institutionalization of this discipline in the second half of the twentieth century was largely the result of a confluence of events happening at mid-century, the most notable of which was the rise of an international population control movement. Sufficient resources were available for a long enough period to establish an academic discipline that became self-sustaining.

Twenty-first century demography, however, still lacks some characteristics of a fully mature discipline. Its disciplinary cohesiveness arises more from having a well-defined subject matter, a distinctive set of data sources, and a focus on common policy issues rather than from having a unifying theory capable of linking societal and individual demographic behavior. Because most populations have completed or are near completing their mortality and fertility transitions they experience common trends: population aging in nearly every region; below replacement fertility in much of the North; declining population growth in much of the South. For the moment these common trends have produced a policy environment with few ideological divides and the discipline's immediate twenty-first century prospects appear secure.

New disciplinary challenges, however, can be seen on the horizon. Demography traditionally has used its distinctive data sources and analytical tools to define itself. Those who analyze census data and vital statistics using projection modeling or life table techniques are 'demographers.' Countries, however, are increasingly using surveys, not censuses, to generate demographic data. Studies of contemporary changes in sexual behavior, marriage, fertility, household composition, morbidity, mortality, education, income, and employment increasingly analyze household survey data using standard statistical techniques. The boundaries separating demography from economics, sociology, and other social sciences are blurring as more of these studies are undertaken by individuals who do not self-identify as 'demographers.' With theory playing such a limited role in defining demography, it is unclear if a distinct discipline will remain as its data and methods become less unique.

It is also unclear how long the tranquil ideological environment now surrounding most contemporary demographic research will remain in place. The discipline evolved in a funding environment in which population specialists focused on the demographic trends that troubled Western policy makers and devised policy interventions aimed at solving their population problems. With much of the world proceeding on a course of demographic change similar to that initially experienced by the West, the discipline's general policy relevance gradually expanded to encompass wider territories. But the economic and demographic convergence occurring in the twenty-first century is already giving birth to a multipolar political world in which countries and regions are developing distinctly different and oftentimes competing population interests. The OECD estimated that the US, Japan, and Europe produced 37% of the world's GDP in 2011, while India and China produced 24%. It projects that by 2060 the US, Japan, and Europe's share of the world's GDP will drop to 28%, whereas India's and China's share will increase to 46%. Less developed economies are growing faster than more developed economies, and by century's end their average resident is predicted to have a higher per capita income than is found today in more developed economies. A new economic pyramid is already emerging and significant shifts in countries' economic rankings are likely to become more noticeable as the century progresses.

Demographic changes are only magnifying the significance of the economic rise of the South. The UN estimates that the 'more developed' world contained 18% of the world's population in 2011 but predicts that its share will fall to 13% by 2060 as Europe's share slips from 11 to 7% while Africa's share increases from 15 to 28%. Although the UN foresees a general global convergence of fertility by century's end to around two children per woman, since the South is experiencing its fertility transition at a later time, the result will be a future world in which Southern citizens constitute the great majority of the population. In the twentieth century the overwhelming economic dominance of the West lessened the importance of relative human numbers. A country in which a large majority of citizens were impoverished had little political clout even if its population was quite large. But the economic and demographic rise of the South in the twenty-first century is producing a new political environment in which democratic ideals and political clout are much more closely aligned. In a world that privileges democratic norms and in which each individual's economic weight is becoming more equal, relative human numbers assume a greater political significance.

The long-term prospects of demography, therefore, will depend on how skillfully it can negotiate the new multipolar political world that is emerging as the North's demographic and economic importance recedes. Demography always has had to prove itself in terms of its policy relevance, but it no longer has an easily defined principal client. If pursuit of national interests simply is assumed to be demography's raison d'être, with US demographers working to help craft the best migration policies for the United States while Mexican demographers do the same for Mexico, then population policy conflicts will become the norm and demography will lose some of its scientific luster. In truth, the new physical world that is emerging as a result of twenty-first century economic and demographic changes requires a new policy focus for the discipline. An enlarged human population consuming natural resources at increasing per capita rates has already generated disruptive climate changes that recognize no national boundaries. Shortages of vital resources, especially of water, appear likely as the century progresses. If demography is to have the capability of offering humankind a way of negotiating the population/environment policy challenges of the twenty-first century, then it needs to adopt the world as its principal client. Then demography might be the source of objective policies to move populations away from rising coastlines or to resettle those who find themselves living in increasingly inhospitable areas. It is not clear that demography as presently constituted is equipped for such tasks.

Dependency in Language

Abstract

The notion of linguistic dependency is introduced with three major types: semantic, syntactic, and morphological dependencies. Semantic dependency [= Sem-D] is a relation between a predicate semanteme 'σ_1' and its argument semanteme 'σ_2' or between two lexemes L('σ_1') and L('σ_2'). Syntactic dependency [= Synt-D] is a relation between two lexemes defined by three groups of formal criteria: (A) Criterion for the *presence* of Synt-D; (B) Criteria for the *direction* of Synt-D; and (C) Criteria for the *type* of Synt-D. Morphological dependency [= Morph-D] is a relation between two lexemes defined by the imposition of a grammeme by one lexeme upon another; this dependency type appears either as agreement or as government. The three types of dependency can combine, producing 14 possible combinations of dependencies between two given lexemes in an utterance. Dependency and constituency are cursorily compared; several linguistic phenomena whose description is more conveniently done in terms of dependency are considered (valence and voice, lexical functions, phraseology, paraphrasing, word order).

Notion of Linguistic Dependency

Consider an English Sentence, for Instance, (1):

(1) *The boys care for their mother*

As any sentence in any language, it is organized by syntagmatic relations that hold between its words and are involved in (i) arranging words in linear strings, (ii) supplying them with appropriate prosody, and (iii) giving them a necessary morphological form. (Syntagmatic relations are opposed to paradigmatic relations, holding between words in the language – not in a sentence – and involved in choosing semantically/syntactically appropriate words to be used in sentences.)

The main type of syntagmatic relation in any language is dependency: in a sentence of language L, lexical unit L_2 (syntactically) depends on lexical unit L_1 if and only if L_1 and L_2 can form a phrase of L and L_1 determines L_2's presence and linear position in the sentence under examination (for details, see Section Syntactic Dependency [= Synt-D], Criterion A); we also say that L_1 is the syntactic governor of L_2. Thus, in (1), the noun *boys* depends on the Main Verb [= MV] *care*: *boys care* is a phrase of English, and, as the syntactic subject, *boys* must precede the MV; *for* also depends on *care*: if MV were *thinks* or *likes*, the preposition should be *of*, respectively, nothing, and *for* must follow *care*; *mother* depends on *for*, since *mother* is positioned with respect to it; etc. Dependency D is symbolized with an arrow pointing from the governor to the dependent: *boys*←*care*, *care*→*for*, *for*→*mother*. D is an antireflexive and antisymmetrical binary relation (= 'X depends on Y'):

- no L can depend on itself: $\neg L \leftarrow L$ (antireflexivity);
- if L_2 depends on L_1, then L_1 cannot depend on L_2: $L_1 \rightarrow L_2$ entails $\neg L_2 \leftarrow L_1$ (antisymmetry).

Transitivity of D varies for different types of dependency; it will be characterized later.

Some syntagmatic relations in language are not dependencies, e.g., coreferentiality: in (1), *boys* and *their* have the same referent; this relation is reflexive, symmetrical, and transitive.

Three Major Types of Linguistic Dependency

Speaking about dependency, people often mean just syntactic dependency. Thus, the sketchy analysis of example (1) presented above illustrates syntactic dependency. However, there are three different types of linguistic dependency: semantic, syntactic, and morphological dependencies (Mel'čuk 1981, 1988: 105ff., 2009: 8–66).

Semantic Dependency [= Sem-D]

The lexeme L_2 semantically depends on the lexeme L_1 in the semantic structure of a sentence, i.e., L_1–**sem**→L_2, if and only if [= iff] the meaning of L_1 is a predicate and the meaning of L_2 is an argument of it; in other words, L_1–**sem**→L_2 means '$L_1(L_2)$.'

A Sem-dependent of a lexeme is called its semantic actant [= SemA] (for actants, see Mel'čuk 2004a,b).

Properties of Semantic Dependency

Like all Ds, Sem-D is antireflexive; like Synt-D, it is antisymmetrical. As for transitivity, Sem-D is neither transitive nor antitransitive: in most cases, L_1–**sem**→L_2 and L_2–**sem**→L_3 entail neither L_1–**sem**→L_3 nor ¬(L_1–**sem**→L_3). Figure 1 shows possible transitivity of Sem-D, and Figure 2, its possible antitransitivity.

The structural words TO and FOR are not represented in the SemS since they are semantically empty – their role is to mark syntacic links, not carry meaning.

Figure 1 The semantic structure of the sentence *Mary ordered John to go*

Figure 2 The semantic structure of the sentence *John cares for Mary*

Sem-Ds are labeled: a Sem-D arc carries a distinguishing symbol identifying the corresponding Sem-actant.

Sem-D does not presuppose the uniqueness of the governor: a lexeme can semantically depend simultaneously on more than one lexeme, cf Figure 1: 'John.'

Sem-D is linguistically universal: it is present in all languages, appears in all sentences of a language, and embraces all full lexemes of a sentence. In a sentence, Sem-Ds form a connected structure (there is a Sem-D 'path' between any two lexemes of the sentence); the semantic structure [= SemS] is a network.

Syntactic Dependency [= Synt-D]

Sem-D is mentally perceived by the speakers, and Morph-D (see below) is perceived physically; but Synt-D, which mediates between them, is not directly perceivable. It is an abstract construct that must be specified by some formal criteria.

Criteria for Synt-D

To establish a Synt-D relation between lexemes L_1 and L_2 in a sentence, three groups of criteria are needed – namely, A: Criterion for Synt-connectedness (= for the presence of a Synt-D); B1–3: Criteria for the Synt-dominance (= for the orientation of the Synt-D); and C1–3: Criteria for the specific type of the Synt-D.

Criterion A: Synt-Connectedness

For L_1 and L_2 to be syntactically directly linked (that is, for there to be L_1–**synt**–L_2), Criterion A must be satisfied.

Potential Prosodic Unity and Linear Disposition

In a given sentence of L, lexemes L_1 and L_2 have a direct Synt-D link iff both conditions 1 and 2 are satisfied:

1. a. **General case**: Either L_1 or L_2 can form a phrase in L.
   b. **Special case**: Or L_1 and L_2 cannot form a phrase in L, but L_1, L_2, and L_3 can, such that in the phrase L_1–L_2–L_3 the Synt-head is L_1 and L_2 and L_3 also form a phrase in which the Synt-head is L_2 (for the concept of Synt-head, see immediately below).
2. The linear position of one of the lexemes, L_1 and L_2 or, more precisely, of the corresponding wordforms, w(L_1) and w(L_2) must be specified with respect to the other: w(L_2) either precedes or follows w(L_1), or else can precede or follow it – freely or under some conditions.

Examples

General case: N + V (*John snores*), V + ADJ (*was sick*), V + N (*see John*), PREP + N (*for John*), ADV + ADJ (*extremely intelligent*), etc.

Special case: For example, *escape* [L_1] *from* [L_2] *problems* [L_3], where *escape from problems* is a phrase of English, with *escape* being its Synt-head; *from problems* is also a phrase in which *from* is the Synt-head; therefore, *escape* and *from* have – within the phrase *escape from problems* – a direct syntactic link: *escape*–**synt**–*from*. Note that mentioning (in Criterion A) the syntactic head, which was not yet defined, does not violate logical consistency: first, the head in the phrases L_1–L_2–L_3 and L_2–L_3 is established in due course, and only then are these phrases used to establish the prosodic unity for L_1–L_2.

Criteria B1–3: Synt-Dominance

In a phrase L_1–**synt**–L_2, one of the two lexemes is the Synt-governor of the other (and the Synt-head of the phrase): the Synt-governor is the lexeme that determines, to a greater extent than the other (its Synt-dependent), the syntactic, morphological, and semantic properties of the phrase.

Criterion B1: The Passive Synt-Valence of a Phrase

The passive Synt-valence of an expression *X* is a set of syntactic constructions of L in which *X* can appear as an addition to the corresponding construction. To put it differently, you take a correct utterance of L and add *X* to it, so that the correctness of the utterance is not violated and its meaning is not deformed, but enriched. For instance, an ADJ(ective) such as *white* can be added to a N(oun), say, *white leaf*, or to a copula verb, producing *is/seems white*; the passive valence of an ADJ is a set including N, $V_{(copula)}$, etc. The passive valence of a phrase ADJ + N is that of the N, not that of the ADJ, since this phrase can be used in all the contexts where an N can, but not in all the contexts where an ADJ is usable.

In a phrase L_1–**synt**–L_2, the lexeme L_1 is the Synt-governor of L_2 if the passive valence of the whole phrase is determined to a greater extent by the passive valence of L_1 than by that of L_2. L_1 is also called Synt-head of the phrase.

The Synt-head of a phrase determines the possible external syntactic links of the phrase more than any other of its wordforms.

(2) a. The passive valence of the phrase *for decades* is fully determined by the preposition (= it can be used where this preposition is allowed); therefore, *for*–**synt**→*decades*.
   b. A phrase like *has escaped* or *does not escape* plays the same Synt-role as *has/does* rather than that of *escaped* or *escape*; therefore, *has*–**synt**→*escaped*, *does*–**synt**→*escape*.

In case L_1 and L_2 have the same passive syntactic valence, Criterion B1 does not supply an answer, so that Criterion B2 has to be used.

Criterion B2: Morphological Links between the Lexemes of a Phrase and Its External Context

In a phrase L_1–**synt**–L_2 (in which the passive Synt-valence does not allow us to establish the Synt-governor), L_1 is the Synt-governor of L_2 if L_1 controls the inflection of lexemes external to the phrase or if L_1's own inflection is controlled by such lexemes.

(3) The phrase Rus. *jubka-štany* lit. 'skirt-pants' does not allow for the application of Criterion B1; but Criterion B2 singles out *jubka* as the Synt-governor: *èt* + ***a*** FEM.SG *jubka-štany byl* + ***a*** FEM.SG ... 'this skirt-pants was...,' where the agreement is with *jubka* FEM.SG, and not with *štany* PL ⟨**èt* + ***i*** *jubka-štany byl* + ***i***...⟩; therefore, *jubka*–**synt**→*štany*.

In case L_1 and L_2 have the same morphological properties, Criterion B2 does not supply an answer and Criterion B3 has to be used.

Criterion B3: The Semantic Content of the Phrase

In the phrase L_1–**synt**–L_2 (in which neither the Synt-valence nor the morphology allow us to establish the Synt-governor), L_1 is the Synt-governor of L_2 if the denotation of L_1–**synt**–L_2 is a subset of the denotation of L_1 rather than a subset of the denotation of L_2.

By denotation of L is understood the set of all its possible referents. In other words, L_1–**synt**–L_2 means 'a kind/an instance of L_1,' and not 'a kind/an instance of L_2.'

(4) a. In the phrase *jam sandwich*, the Synt-governor is *sandwich*, because "*jam sandwich* refers to a kind of sandwich, rather than to a kind of jam" (Hudson, 1990).

b. In the Mandarin Chinese phrase [*shí*] *bàng ròu* '[ten] pounds [of] meat,' *ròu* 'meat' is the Synt-governor: [*shí*] *bàng ròu* refers to meat, not pounds; therefore,

[*shí*←**synt**–]*bàng*←**synt**–*ròu*.

Both lexemes *bàng* and *ròu* are nouns – that is, they have the same passive syntactic valence, and Chinese has no inflection.

The Synt-governor is thus the syntactic class determinant, or (if there is no syntactic determinant) the morphological behavior determinant, or (in case both syntactic and morphological determinants are absent) the semantic content, i.e., denotation, determinant (1993: 295-296).

Although most approaches dealing with Synt-Ds require concord between these three properties, i.e., between Criteria B1–3, such a concord should not be expected. Only Criterion B1 is genuinely syntactic; B2 is morphological; and B3 semantic. It is well known that orientations of Sem-D, Synt-D, and Morph-D between two wordforms can differ (cf Section Possible Combinations of the Three Types of Linguistic Dependency below); therefore, these criteria are often in conflict. Criteria B1–3 form a hierarchy: B1 > B2 > B3. If B1 is applicable, its indication is sufficient. Only if it is not applicable, B2 applies – in L having inflection and for L_1 and L_2 with different morphological properties. Otherwise, B3 applies. Therefore, Criteria B1–3 are never applied simultaneously and thus cannot contradict each other.

For Criteria B to be satisfied, at least one of Criteria B1–3 must be satisfied.

The criteria for the orientation of Synt-D ('Head vs Dependent' problem) are discussed in Zwicky (1985, 1993), Hudson (1987, 1990: 106–107), Mel'čuk (1988: 132ff., 2009: 25–40), and Corbett et al. (1993).

Criteria C1–3: Labeled Synt-Dependencies

For each phrase L_1–**synt**→L_2, the type of the Synt-D relation must be established, because to represent the SyntSs of sentences, different types of Synt-D are needed. Thus, I←**synt**–LOVE–**synt**→YOU does not distinguish between 'I love you' and 'You love me.' In all such cases, different types of Synt-D, or different syntactic relations [= SyntRels], are needed: I←$\mathbf{r_1}$–LOVE–$\mathbf{r_2}$→YOU, $\mathbf{r_1}$ = **subjectival**, and $\mathbf{r_2}$ = **direct-objectival**. (Recall that the nodes of a SyntS are not linearly ordered and the markers of syntactic roles – such as grammatical cases – are not shown in it, exactly because word order and cases are **exponents** of Synt-Ds, which a SyntS represents.)

SyntRels are labeled, and the label **r** of a SyntRel denotes a family of syntactic constructions that implement the SyntRel **r**.

NB: As shown in Section Deep- versus Surface-Syntactic Structure and Deep- versus Surface-Syntactic Relation below, two syntactic levels are distinguished: a deep-syntactic and a surface-syntactic level, so that in fact there are two corresponding families of Synt-Ds – namely, deep- and surface-syntactic dependencies. To keep things as simple as possible, this section considers only the surface-syntactic dependencies.

Thus, the SSynt-label «**subjectival**» just mentioned identifies a set of SSynt-rules that (in English) linearly position the noun L_2 with respect to the verb L_1 – in a neutral context, before it – and make L_1 agree with L_2 in person and number (L_2 is of course the syntactic subject).

In the phrases L_1–**r[?]**→L_2, the SSynt-D that links the two wordforms can be labeled **r** only if it satisfies all of the following criteria C1–3; if one of them is not satisfied, the presumed SyntRel **r[?]** must be split into different SSyntRels $\mathbf{r_1}$ and $\mathbf{r_2}$.

Criterion C1: Absence of Semantic Contrast [w(L) Stands for 'a Wordform of Lexeme L']

A SSyntRel must not describe two phrases $\mathbf{w_i}(L_1)$–**synt**→$\mathbf{w_j}(L_2)$ and $\mathbf{w_m}(L_1)$–**synt**→$\mathbf{w_n}(L_2)$, which:

i. contrast semantically – that is, '$\mathbf{w_i}(L_1)$–**synt**→$\mathbf{w_j}(L_2)$' ≠ '$\mathbf{w_m}(L_1)$–**synt**→$\mathbf{w_n}(L_2)$' and

ii. differ formally by purely syntactic means of expression, i.e., only by word order, syntactic prosody, or syntactic grammemes.

(5) The Russian construction PJAT'←**r[?]**–DOLLAR has two implementations with different meanings: *pjat' dollarov* '5 dollars' versus *dollarov pjat'* 'approximately 5 dollars';

the formal difference here is purely syntactic: word order; therefore, the presumed SSyntRel **r[?]** must be split into two different SSyntRels:

PJAT′ ← **quantitative** – DOLLAR ⇔ *pjat′ dollarov*
PJAT′ ← **approx-quantit** – DOLLAR ⇔ *dollarov pjat′*

Criterion C1 corresponds to the Minimal Pair Test, widely used in linguistics.

Criterion C2 deals with the substitutability of syntactic subtrees. The use of this property as a criterion for establishing SyntRels was proposed in Kunze (1975: 235ff.); hence the name: the Kunze property. Here, however, a weaker version of it is used: the quasi-Kunze property.

The quasi-Kunze property [$\Delta_{(X)}$ is a subtree with the top node of the syntactic class X]:

A SSyntRel **r** has the quasi-Kunze property iff there exists in L a syntactic class X such that for any SSynt-configuration L-**r**→$\Delta_{(Y)}$, replacing $\Delta_{(Y)}$ by $\Delta_{(X)}$ (but not necessarily vice versa!) in any SSynt-structure does not affect its syntactic well-formedness.

In other words, for a SSyntRel **r** having the quasi-Kunze property it is always possible to indicate such a prototypical dependent that it will be admitted by any eventual governor.

Criterion C2: Syntactic Substitutability

Any SSyntRel **r** in L must possess the quasi-Kunze property.

(6) In the phrases *have*–**r[?]**→*been* and *be*–**r[?]**→*going* the presumed SSyntRel **r[?]** does not possess the quasi-Kunze property:
have–**perfect-auxiliary**→*been* and *be*–**progressive-aux**→*going*, but not
have*–synt**→*going* or **be*–**synt**→ *been*.

Criterion C2 is a particular case of the Substitution Test: it deals with the substitution of subtrees that hang on the same SSyntRel **r**.

Criterion C3 takes into account the fact that a SSyntRel of language L can be either nonrepeatable or unlimitedly repeatable.

Nonrepeatable SSyntRels

A SSyntRel **r** is nonrepeatable iff no more than one branch labeled **r** can start from any governor.

Actantial SSyntRels, which describe the Subjects, the Objects, and the Complements, are nonrepeatable. (In some languages, an actant can/must be 'duplicated' by a resumptive pronoun, but such duplication is not considered as repeatability: it has a completely grammaticalized character.)

Unlimitedly Repeatable SSyntRels

A SSyntRel **r** is (unlimitedly) repeatable if and only if several branches labeled **r** can start from a governor.

For a repeatable SSyntRel **r**, the number of branches labeled **r** starting from a governor is theoretically unlimited, although practically it is, of course, limited by pragmatic considerations or the properties of governors. For instance, the **modificative** and **circumstantial** SSyntRels in English are unlimitedly repeatable.

Criterion C3: Repeatability with the Same Synt-Governor

Any SSyntRel **r** must be either unlimitedly repeatable or non-repeatable – that is, it cannot be limitedly repeatable.

(7) In Persian, expressions of the following type are extremely widespread: *Raminra bedar kärd* '[He/She] awoke Ramin' lit. '[He/She] Ramin awakening made.' This sentence has the Synt-structure as follows:
Ramin+ra ← **r[?]**–*kärd*–**r[?]**→*bedar*
DirO made awakening [Noun]

A verbal collocation of the type *bedar kärd* 'awakening make' = 'awake' or *därs däd* lit. 'lesson give' = 'teach' seems to contain a DirO (*bedar* or *därs*), but behaves as a normal transitive verb and takes a 'genuine' DirO (with the suffix **-ra**). The presumed SSyntRel **r[?]** here would be limitedly repeatable – just twice. Therefore, there are two different SSyntRels:

RAMIN ← **dir-obj**–KÄRD–**quasi-dir-obj** → BEDAR.

The nominal base of the collocation in question is a quasi-direct object.

Criterion C3 corresponds to the Cooccurrence Test: an element of a grammatical category is

- either nonrepeatable, like tense or number in English;
- or unlimitedly repeatable, like the causative in Turkish: *uyu-* 'sleep' ~ *uyu-**t**-*'cause to sleep' (e.g., by rocking) ~ *uyu-**t-dur**-* 'cause to cause to sleep' (e.g., by telling somebody to make the baby sleep') ~ *uyu-**t-dur-t**-* 'cause to cause to cause to sleep' (e.g., by reminding a person to tell somebody to make the baby sleep).

Notion of Synt-D and Dependency Tree as the Formalism for Representing Syntactic Structures

Now the definition of SSynt-D can be formulated.

Surface-Syntactic Dependency [= Synt-D]

In a given sentence, the lexeme L_2 syntactically depends on the lexeme L_1 via SSyntRel **r**, i.e., L_1–**r**→L_2, iff Criteria A, B, and C are satisfied for this pair of lexemes and **r**.

The lexeme L's SSynt-dependent that satisfies some particular conditions (roughly speaking, it corresponds to L's SemA), is L's SSynt-actant [= SSyntA] (Mel'čuk, 2004b).

For a different definition of Synt-D, see Gerdes and Kahane (2011) (where, among other things, dependency is generalized to represent the structure of discourses as well as the internal structure of wordforms).

Properties of Syntactic Dependency

Like Sem-D, Synt-D is antireflexive and antisymmetrical: ¬(L_1–**synt**→L_1); L_1–**synt**→L_2 entails ¬(L_1 ← **synt**–L_2). It is also antitransitive: within one sentence, L_1–**synt**→L_2 and L_2–**synt**→L_3 entail ¬(L_1–**synt**→L_3). Thus, Synt-D presupposes the uniqueness of the governor: a wordform either can syntactically depend on only one other wordform or be syntactically independent, as is the top node of a syntactic structure [= SyntS]. This requirement is based on a simple consideration: Synt-D ensures linear ordering of lexemes in the sentence, and a lexeme can be ordered – before or after – with respect to only one other lexeme.

Figure 3 Surface-syntactic structure of sentence (1).

Synt-Ds are labeled: to properly represent *Mary loves John*, in the phrases *Mary*←$\mathbf{r_1}$–*love* and *John*←$\mathbf{r_2}$–*love* two different SSyntRels, $\mathbf{r_1} \neq \mathbf{r_2}$, are needed.

Synt-D is linguistically universal: it is present in all languages, appears in all sentences of a language, and embraces all wordforms of a sentence. In a sentence, Synt-Ds form a connected structure, which formally is a dependency tree: a connected graph where (i) each node, except one, depends on only one node (= the uniqueness of the Synt-governor) and (ii) one and only one node does not depend on anything (= the uniqueness of the top node, or the root, of the tree).

Thus, SyntSs of sentences are described by dependency trees. The linear order of the nodes in a SyntS is not defined; the D-description consistently separates the Synt-links between wordforms and their linear order. Elements of a D-tree are labeled: nodes with the names of lexical units supplied with grammemes, and branches with the names of Synt-relations – that is, particular Synt-Ds. See the Surface-Syntactic Structure of sentence (1) in Figure 3:

Deep- versus Surface-Syntactic Structure and Deep- versus Surface-Syntactic Relations

At the syntactic level of linguistic representation (as well as at the morphological and phonic levels), two sublevels are distinguished: Deep-Syntactic [= DSynt-] versus Surface-Syntactic [= SSynt-]. DSynt-structure is geared to meaning: it reflects explicitly all syntactically relevant semantic distinctions and ensures maximally smooth transition between the SemS and itself; SSynt-structure is oriented toward the physical shape of the sentence: it presents explicitly all formal contrasts and ensures smooth transition between itself and the linearly ordered Deep-Morphological structure of the sentence. Both Synt-structures are D-trees differing by the labeling of nodes and branches: deep lexical units versus surface lexical units with corresponding grammemes; DSyntRels (language-universal, a dozen) versus SSyntRels (language-specific, a few dozen).

Deep-Syntactic Relations

A DSynt-relation is a generalization over several actual syntactic constructions found in natural languages; all DSyntRels taken together are expected to cover all syntactic constructions known at present. The set of DSyntRels is determined by the following five DSynt-oppositions:

1. *Coordination versus Subordination*: coordinate versus subordinate constructions; the former are represented by the DSyntRel COORD [*honey*–COORD→*and cinnamon*] and QUASI-COORD [*yesterday*–QUASI-COORD→*at 3 o'clock*]. (The QUASI-COORD DSynt Rel represent several constructions that formally resemble coordination: *in Spain, on the South Coast, in a small village; one summer, in June; 10 dollars* (*and*) *55 cents.*)
2. *Weak versus Strong Subordination*: constructions with weak versus strong structural links between sentence elements; the former are represented by the DSyntRel APPEND(itive) [*He is,*–APPEND→*unfortunately, absent*].
3. *Modification versus Complementation*: modification is a type of Synt-D such that in the phrase L_1–**synt**→L_2 the Sem-D goes in the opposite direction: 'L_1←**sem**–L_2'; complementation is a type of Synt-D such that in the phrase L_1–**synt**→L_2 the Sem-D goes in the same direction: 'L_1–**sem**→L_2.' The DSyntRels of the first class are ATTR(ibutive) [*He works*–ATTR→*hard*]; the DSyntRels of the second class are actantial.
4. *Restrictive versus Descriptive Modification*: the former is represented by the DSyntRel ATTR (which by default is understood as restrictive): *He reads only* ***interesting*** ⟨***Spanish***⟩ *books*; the latter is represented by the DSyntRel $\text{ATTR}_{\text{descr}}$: *These three students,* ***who just returned from Europe****, were selected to represent the department.*
5. *Different Actantial Roles*: **I**, **II**, …, **VI**, $\mathbf{II}_{\text{dir.sp}}$. Constructions with actantial DSyntRels are divided into seven classes: the empirically determined maximal number of DSyntAs that a lexical unit in natural language can have is six, plus a special DSyntRel for Direct Speech, as in '*Never*!'←$\mathbf{II}_{\text{dir.sp}}$–*whispered*–**I**→*Alan*.

The full inventory of DSyntRels is represented in Figure 4:

Surface-Syntactic Relations

In sharp contrast to DSyntRels, Surface-Syntactic relations describe real syntactic constructions of a particular language; they have to be empirically established for each language, just like its phoneme inventory or the set of its grammatical cases. The methodology is, generally speaking, the same as that used for establishing any linguistic units (Iordanskaja and Mel'čuk, 2009): (i) determining a list of relevant syntactic properties of lexical units for the given language L (such as being obligatory in any clause, being combinable with a finite verb only, being cleftable, being relativizable, being dislocatable, being the

controller of agreement, being the controller of reflexivization, being sensitive to negation, etc.); (ii) partitioning all syntactic constructions of L into families according to the similarity of their relevant syntactic properties; (iii) associating each family thus obtained to a SSyntRel; (iv) checking the set of established SSyntRels against the above criteria; (v) cyclically repeating the procedure – modifying the starting list of properties, changing the distribution of constructions between families, etc., until an acceptable set of SSyntRels is obtained.

Here is a tentative list of 54 SSyntRels of English, compiled on the basis of Mel'čuk and Pertsov (1987: 85–156) and Mel'čuk (2009: 52–58), and also taking into consideration Apresjan et al. (1989: 71–121).

Morphological Dependency [= Morph-D]

The lexeme L_2 morphologically depends on the lexeme L_1 according to the inflectional category CAT, i.e., L_1–**morph**/CAT→L_2, iff at least one grammeme G of L_2, such that G ∈ CAT, is determined by L_1.

L_1 is called the controller of L_2, and L_2 the target of L_1.

Two major types of Morph-D are known: agreement (including a particular case: congruence of a pronoun with its antecedent) and government.

Properties of Morphological Dependency

Like Sem-D and Synt-D, Morph-D is antireflexive: the inflection of a lexeme in a sentence cannot be determined by the lexeme itself. Like other Ds, Morph-D is also antisymmetrical, although in a more complex sense than in case of Sem-D and Synt-D: one has to take into account the inflectional category whose grammeme is imposed by the controller. Thus, L_1–**morph**/CAT→L_2 entails ¬(L_1←**morph**/CAT–L_2). However, for two different inflectional categories $CAT_1 \neq CAT_2$, the following situation is possible: L_1–**morph**/CAT_1→L_2 and, at the same time, L_1←**morph**/CAT_2–L_2; here is an example:

(8) Rus. *dv*+***a*** *stol* +***a*** 'two tables'
    two MASC.NOM table$_{(masc)}$ SG.GEN
    The noun form *stola* morphologically depends for its singular and genitive case on *dva*, while *dva* morphologically depends on *stola* for its masculine gender; cf *pjat' stol* + ***ov*** PL.GEN 'five tables' or *dvadcat' odin stol*+***Ø*** SG.NOM lit. 'twenty-one table,' but *dv*+***e*** FEM.NOM *krovati*$_{(fem)}$ 'two beds.' (In Russian, a quantified N after a numeral Num in the nominative or the inananimate accusative is in the singular genitive, if this Num ends in 2, 3 or 4, and in the plural genitive, if the Num ends in 5 or a bigger number; if the Num ends in 1, the N is in the singular.)

Like Sem-D and Synt-D, Morph-D is labeled in the sense that, in order to fully specify a Morph-D, we have to indicate the inflectional category of L_2 whose grammeme is imposed by L_1.

Morph-D does not presuppose the uniqueness of the governor: a wordform can morphologically depend simultaneously on several wordforms (but, as was indicated, for different inflectional categories).

Morph-D is not linguistically universal: it is not present in many languages at all – languages that have neither agreement nor government (e.g., Chinese or Vietnamese); in a language where it exists, it is not present in all sentences; and in a sentence where it is present it does not necessarily embrace all wordforms. Morph-Ds do not form, generally speaking, a connected structure in a sentence.

Possible Combinations of the Three Types of Linguistic Dependency

The semantic, syntactic, and morphological dependencies are reciprocally autonomous and can co-occur in 14 logically possible combinations (Mel'čuk, 1981, 1988: 118–128, 2009: 58–65; Nichols, 1986). Here are illustrations of some of these combinations.

CASE 1: L_1 L_2, i.e., no syntagmatic dependency between two wordforms.

Example: *the* and *mother* in (1).

CASE 3: L_1 **synt**→L_2, i.e., Synt-D without any Sem-D or Morph-D.

(9) a. In Japanese, a quantifier, while bearing semantically on the Subject as in '**Five** people were injured,' depends syntactically on the verb, with which it has neither semantic nor morphological links (semantically, *gonin*

bears on *keganin*, while morphologically *gonin* depends on it for its classifier):

Sono ziko +de keganin +ga
this accident LOC injured.people SUBJ(ective)
go +nin *deta*
five CLASS(ifier) emerged
'In this accident, five people were injured.' = lit. '…injured.people five-ly emerged.'

b. In English, a measure noun used as a DirO depends syntactically on the verb, but has no semantic or morphological link with it (semantically, the verb dominates the noun quantified):
John bought–[*five*]–**synt**→***kilos*** [*of potatoes*].

CASE 6: $L_1 \begin{smallmatrix}\text{—sem}\rightarrow\\ \leftarrow\text{synt-}\end{smallmatrix} L_2$, i.e., Sem-D and Synt-D oriented the opposite ways, with no Morph-D.
Example: an adjective and the modified noun in an ADJ + N phrase in a language with invariant adjectives, cf *new* and *areas* in *new areas*.

CASE 8: $L_1 \begin{smallmatrix}\text{—sem}\rightarrow\\ \leftarrow\text{morph-}\end{smallmatrix} L_2$, i.e., Sem-D and Morph-D, oriented the opposite ways, with no Synt-D.
Example: an attributive adjective in a language with adjective agreement.

(10) Fr. *Marie semblait* ***fatiguée*** 'Marie seemed tired.'
Semantically, *Marie* depends on *fatiguée* ['fatigué–**sem**→Marie'], but morphologically, *fatiguée* depends on *Marie* for its singular and feminine; syntactically, the two lexemes are not directly linked.

CASE 13: $L_1 \begin{smallmatrix}\text{—sem}\rightarrow\\ \text{—synt}\rightarrow\\ \leftarrow\text{morph-}\end{smallmatrix} L_2$, i.e., Sem-D and Synt-D oriented the same way, while Morph-D is opposite.
Example: a Main Verb and its nominal actants in a caseless language with polypersonal agreement of the MV.

(11) Abkhaz *Sara Nadš'a* ***i+l*** *+əs+teit'* *aš*^{w}*q*^{ʷ}*aə*
I it her I gave book
'I gave Nadsha [a] book.'

CASE 14: $L_1 \begin{smallmatrix}\text{—sem}\rightarrow\\ \leftarrow\text{synt—}\\ \leftarrow\text{morph-}\end{smallmatrix} L_2$, i.e., Synt-D and Morph-D are oriented the same way, while Sem-D is opposite.

Example: an adjective and the modified noun in a language with adjectival agreement, where the adjective bears semantically on the noun, but syntactically and morphologically depends on it, e.g., Lat. *bon* + ***a***$_{\text{FEM.SG.NOM}}$ *urb*$_{\text{(fem)}}$ + ***s***$_{\text{SG.NOM}}$ 'good city' ~ *bon* + ***arum***$_{\text{FEM.PL.GEN}}$ *urb*$_{\text{(fem)}}$ + ***ium***$_{\text{PL.GEN}}$ 'of.good cities.'

Syntactic Dependency and Syntactic Constituency

General Remarks

Before the appearance of the dependency approach to syntax (early 1960s), the mainstream syntactic investigations were based on constituency, or phrase structure – the staple diet of Bloomfieldean structuralism and then of Chomskyan generative-transformational grammar. At the beginning, it was believed that dependency and constituency were two different legitimate ways of describing the syntactic structure of sentences. Padučeva (1964) and Gaifman (1965) studied formally the mathematical equivalence of D-approach with constituency, or C-, approach, and formulated conditions under which they can in fact be made equivalent. For systematic comparison of both approaches, see Vennemann (1977), Hudson (1980a,b), Dahl (1980), Matthews (1981: 71–95), Mel'čuk (1988: 13–17, 2009: 89–92), Sgall and Panevová (1988–89), Rambow and Joshi (1997), and Langacker (1997). However, as time was passing and more studies and descriptions were published, it became increasingly clear that there are serious difficulties with constituency, for instance:

- Constituents, which essentially are groups of words with particular properties, function in language as a **means** used to express the syntactic structure of a sentence; therefore, they cannot be part of the syntactic structure, let alone the main formalism for its description.
- Constituents are not sufficient to univocally express any syntactic structure. The specification of the head element in a constituent and, in some cases, the type of relation between it and other elements have to be added. But as soon as this is done, we obtain, in point of fact, a dependency structure (with some useless 'architectural excesses').
- Constituents do not allow one to distinguish, in a natural way, the purely **syntactic** hierarchy of sentence elements and their **linear** hierarchy (word order).
- Constituents are not convenient for the description of the transition from a semantic structure thought of as semantic network (an equivalent of predicate logic formulas) to a syntactic structure written in terms of constituents.
- Constituents fail in the treatment of several important linguistic phenomena: a stumbling block that warrants a more detailed consideration, see below, Section Linguistic Advantages of syntactic Dependency.

By the end of the past century, constituency representation in syntax was in rapid decline. Langacker (1997) was a *coup de grâce*: the paper explicitly shows that constituents are good only for the (mor)phonological surface, where they take form of familiar prosodic units – phrases, and for conceptual level, where they form conceptual groupings, candidates for unified symbolization; however, constituents are not good for syntax.

Because of these and other similar problems, linguists started very early looking for a hybrid between D- and C-representations (e.g., Vennemann, 1977). The incentive for integration comes from such phenomena as coordination (see Section Syntactic Dependency in the First Half of the Twenty-First Century), extractions (*I know* ***which girl*** *you told my wife Alan was going out with*), analytical forms (*has been detected*), collocations (*make headway*, *pay a visit*, *launch an attack*), and the like. The idea is to introduce for any of these constructions a special type of subtree that is allowed to occupy as a whole one node of a D-tree. The first formal proposal for a mixed D-/C-representation known to me – by means of syntactic groups – was advanced in Gladkij (1966, 1985). The most recent one is Kahane (1997), which introduces the concept of *bubble* (a subset of nodes of a D-tree which is treated as a node, while having inside a completely specified D-structure of its own, including other bubbles).

However, all the difficulties of description that hybrid D-/C-structures try to address are more efficiently overridden by distinguishing deep and surface sublevels of representation, see Section Deep- versus Surface-Syntactic Structure and Deep- versus Surface-Syntactic Relation.

Linguistic Advantages of Syntactic Dependency

Among linguistic phenomena that are quite adequately described in terms of syntactic dependency, but cannot be in terms of constituency, the following five stand out.

Valence, Diatheses, and Voices

A diathesis of a lexeme L is a particular correspondence between L's Sem-actants [= SemAs] and its Deep-Syntactic actants [= DSyntAs]. For instance, the verbs FOLLOW and PRECEDE have inverted diatheses: $X_{\mathbf{I}}$ *follows* $Y_{\mathbf{II}} \equiv Y_{\mathbf{I}}$ *precedes* $X_{\mathbf{II}}$; or, symbolically, X ⇔ **I**, Y ⇔ **II** for FOLLOW and X ⇔ **II**, Y ⇔ **I** for PRECEDE. Such a formulation, as well as the notion itself of actant – on three different levels (SemAs, DSyntAs, and SSyntAs, see Mel'čuk, 2004a,b) – is possible only within a dependency framework.

This description of diathesis leads to a clear definition of voice: a voice is a particular modification of the basic diathesis grammatically marked on the verb. Among other things, the correlation between the active and the passive voices can be represented in the same way: $X_{\mathbf{I}}$ *follows* $Y_{\mathbf{II}} \equiv Y_{\mathbf{I}}$ *is followed by* $X_{\mathbf{II}}$. A calculus of voices can be developed by combining permutations of DSyntAs of L with respect to its SemAs, DSyntAs' suppression, and SemAs' referential identification (see Mel'čuk, 2006: 181–262).

The set of L's actants forms L's active valence, semantic, and syntactic (for passive valence, see above, Section Criteria for Synt-D, Criterion B1 for the orientation of Synt-D). The idea of valence turned out to be a correct metaphor, which spawned many useful solutions. Under the C-approach, this phenomenon has to be described in terms of *subcategorization frame*, thus emphasizing the classification of valence-controlled entities.

Lexical Functions

To describe regular collocations of the type *wield authority*, *pursue a policy* or *honor a commitment*, an inventory of a few dozen Lexical Functions [= LFs] is proposed (Mel'čuk 1996 and 2007); cf Real_1(AUTHORITY) = *wield* [~], Real_1(POLICY) = *pursue* [ART ~], Real_1(COMMITMENT) = *honor* [ART ~], where Real_1 is a verb that means 'to do with N what one is supposed to do with N.' Similarly, for *empty promise*, *poor example* or *pipe dream* we have: AntiVer(PROMISE) = *empty*, AntiVer(EXAMPLE) = *poor*, AntiVer(DREAM) = *pipe* [~], where AntiVer is an adjective that means 'such that it should not be.' An LF is applied to the base of a collocation (in small caps above) and returns the corresponding collocate. LFs, specified for a lexeme in its lexical entry, allow for correct lexical choices under text generation or automatic translation, as well as for efficient paraphrasing, equally necessary for these tasks. No less important is their role in lexicography, as well as in language, teaching, and learning.

The base of a collocation and its collocate are always linked by a particular Deep-Synt-D, specific for a given LF: Real_1(L)–**II**→L, L–ATTR→AntiVer(L), etc.

The LF formalism is only possible based on syntactic D-representation.

Phrasemes

Numerous phrasemes – idioms as well as collocations – do not easily lend themselves to a C-description. Thus, any idiom one of whose Sem-actants depends syntactically on an 'internal' element of the idiom raises a problem: what could a C-structure be of such idioms as LOOSE [X's] COOL, PULL [Y's] LEG, CAT GOT [X's] TONGUE, [X's] GOOSE IS COOKED, DRAG [X's] FEET, etc.? The same problem occurs with all collocations that accept free (= nonidiomatic) modifiers: *kick the* ***filthy*** *habit*, *pull* ***many new*** *strings*, *make an* ***unbelievable*** *headway*, etc. A D-structure for all such expressions is straightforward. O'Grady (1998) said that much, although apologizing for using something that looks like dependencies, but which is 'in fact' just an abbreviation for, as the author says, "more conventional syntactic structure" (p. 284).

Paraphrasing

Expressing the syntactic structure in terms of DS opens the way for powerful paraphrasing – that is, the calculus of sets of semantically equivalent DSyntSs. Such paraphrasing proves to be necessary in translation because of lexical, deep-syntactic, and morphological mismatches between sentences of different languages that translate each other (Mel'čuk and Wanner, 2001, 2006, 2008). An example of mismatches can be seen in the translation of the English sentence (12a) into Russian (and vice versa):

(12) a. *It seems to have stopped raining.*
b. *Dožd,' kažetsja, perestal* lit. 'Rain, [it] seems, stopped.'

The DSyntSs of these sentences and relevant lexical equivalences are given in (12c):

c.

$\mathsf{FinFunc}_0$ in both trees is an LF meaning roughly 'cease to take place'; $\mathsf{FinFunc}_0(\mathrm{RAIN_N})$ = *stop*, while $\mathsf{FinFunc}_0$(DOŽD') = *končit'sja, perestat,' prekratit'sja, projti*.

The DSynt-paraphrasing rules necessary for the transition presented in (12c) are as follows (with serious simplifications):

d. Head-switching Synonymous substitution

The shaded zones represent the context – that is, the elements that are not affected by the given rule, but control its applicability.

Given the limited number of LFs and of DSyntRels, on the one hand, and the fact that all DSynt-transformations are binary, it is possible to develop an exhaustive set of DSynt-

paraphrasing rules, which are cross-linguistically universal (see Mel'čuk, 1992, 2012, 2013; Milićević, 2007).

Word Order

Synt-D is especially convenient for the description of word order: it forces strict separation of the hierarchical (= genuinely syntactic) order from the linear order, the latter being a surface means for the expression of the former. The main task of syntax – linearizing a two-dimensional Synt-structure (Tesnière, 1959: 19–20) – is solved more easily with Synt-Ds:

- Word order rules can be naturally formulated in terms of positioning a Synt-dependent with respect to its Synt-governor.
- One of the most universal properties of word order – so-called projectivity – can be identified and described only in terms of dependency.

Projectivity

(The word order in) the sentence *S* is projective iff in the projection of the SSyntS(*S*) on *S* no dependency arrow crosses another dependency arrow or a projection perpendicular.

Thus, sentence (1) is projective:

(13)

A majority of sentences in actual texts are projective. (Although how big a majority depends of course on the language; according to Havelka (2007): 614, several European languages have, on the average, between 23% and 36% of nonprojective sentences: for instance, Czech – 23.15%, Dutch – 36.44%, German – 27.75%, Slovene – 22.16%, while Chinese has no nonprojective sentences at all, Spanish has only 1.72% and Japanese – 5.29%.) Projectivity allows for simpler and more general word order rules and facilitates computer processing of texts: except for particular cases, only projective sentences must be produced from a given SyntS, and only SyntSs that guarantee projectivity must be associated with a given sentence. However, establishing and describing cases where projectivity violations are permitted or even obligatory is also highly instructive.

For instance, Latin sentence (14a) is nonprojective; cf its SSyntS projected on it in (14b):

(14) a. *Tu solebas meas esse aliquid putare nugas*
[Catullus]
thou used my be something believe trifles
'You used to believe my trifles to be something.'

b.

Shaded circles indicate "crime scenes" – that is, the spots of projectivity violations.

These violations happen because, instead of a 'normal' word order in the sentence *Tu solebas putare meas nugas aliquid esse*, Catullus chose to place the phrase *esse aliquid* before the infinitive *putare* and move the modifier *meas* before this phrase.

Projectivity can be violated in many special cases, for instance:

(15) a. English b. French

The source of nonprojectivity in the English example is the phrase 'in the collection,' which is the actant of the superlative BEST, but must be positioned after the modified noun PAPER; in the French example, it is the relative pronoun DONT 'of which': it depends on AIRE 'area,' but has to be positioned at the beginning of the clause.

Within D-approach, nonprojective constructions pose no problem whatsoever (while C-approach cannot represent nonprojective constructions without additional machinery – e.g., transformations).

- D-approach has the inherent ability to accommodate long-range syntactic links. The perturbations introduced into the word order of a sentence by its Communicative Structure – Frontings, Extractions, Postponings, etc. – can wreak havoc on a C-structure, since even the closest-knit phrases can be torn apart and permuted. But a D-structure, completely free of linearity and contiguity, is insensitive to such permutations; the discontinuities simply do not exist in a D-structure.

Linguistic Insufficiency of Syntactic Dependency: A Case of Coordination

If we use two levels of representation for syntactic structures (Deep-SyntS and Surface-SyntS) plus Communicative Structures on each level, then a pure D-representation in syntax seems to be sufficient for all syntactic phenomena, except for some types of coordination (cf Hudson, 1990: 97ff.). A wordform W may relate either to a whole conjoined phrase or to its Synt-head alone, such that the two constructions are formally distinguished – by syntactic means – and have different meanings; however, within the strict D-approach, both types of structure can be represented only by the direct Synt-D of W on the Synt-head of the conjoined phrase. Consequently, one SyntS corresponds in such cases to two different meanings:

(16) The SyntS *old*←*men*→*and*→*women* can correspond to
– either a joint reading, where the adjective semantically bears on both nouns:
'old {men + women}' = '{old men} and {old women}';

– or a disjoint reading, where the adjective bears on one noun only:
'{old men} and women [who are not necessarily old].'

Different surface implementations that formally distinguish intended meanings are in principle available, for instance, prosody: *old men and women* (without a pause) versus *old men* || *and women*. The semantic contrast accompanied by a formal contrast requires that the semantic distinction be maintained in the SyntS (Criterion C1: p. 3). The only natural way to do so is to complement D-approach with syntactic groupings – specification, within the SyntS, of D-subtrees relevant in such cases (Mel'čuk, 1974: 214–216, 1988: 28–33): *old*←**modif**–*men*→*and*→*women* (without grouping) stands for the disjoint reading, but *old*←**modif**–[–*men*→*and*→*women*] (with a grouping indicated by square brackets) for the joint reading. Note that a grouping is not a constituent: there is no higher node to represent it as a whole, there is no embedding, and it does not participate in D-links as such. The use of groupings makes D-formalism sufficient for all syntactic purposes.

Phrases and Phrase-Like Units in Syntactic Dependency Approach

To sum up: constituents in the strict sense of the term have no place in a dependency description. Nonetheless, dependency syntax uses four types of constituent-like entities.

- Syntactic groupings are closer to constituents than anything else used within D-approach; they are shown in the SyntS. Their deployment is, however, limited to one very specific coordinate construction (and, as just stated, they are not constituents).
- SSynt-rules make use of standard subtrees [= Δ] Mel'čuk and Pertsov, 485–491). For instance, $\Delta_{(NP)}$ is a subtree equivalent to the tree of a noun phrase; it includes, among other things, the trees of the phrases FROM Num_1 TO Num_2 N (*We use* ***from ten to fifteen tons*** [*of concrete*]) or BETWEEN Num_1 AND Num_2 N (*We use* ***between ten and fifteen tons*** [*of concrete*]), etc., which have the distribution of noun phrases; $\Delta_{(VP)}$ is a nonbranching subtree equivalent to a verb (e.g., *might have been sure to cease to handle*); etc. These standard subtrees are convenient abbreviations that allow for the generalization and, at the same time, simplification of SSynt-rules. A standard subtree is of course not a constituent in the classical sense of the term.
- Minimal phrase linear patterns indicate rigid linear arrangements of wordforms within minimal phrases (a minimal phrase is a phrase that does not consist of other phrases); here is, for instance, such a pattern for noun phrases in English: Standard subtrees are used exclusively in word-order rules, not in the syntactic structures.

1	*2*	*3*	*4*	*5*	*6*	*7*	*8*
Coordinate conjunction	Preposition	Demonstrative	Numeral	Possessive adjective	Adjective	Noun	'Formula'
OR	ABOUT	THESE	FOUR	OUR	INTERESTING	EXAMPLES	(11)

or about these four our interesting examples (*11*)

- Actual phrases in the Morph-ProsS of a sentence very closely remind one of constituents: there are continuous segments of speech, separated by pauses (actual and potential) and characterized by specific stresses and intonational contours. For instance:

(17) The DMorph and DMorph-Prosodic Structures of sentence (1):

↗ ↗ ↘
THE BOY_{PL} (|) $CARE_{IND, PRES}$ || FOR THEIR MÓ$THER_{SG}$ |||

Yet they are not constituents, since there is no hierarchy with embedding.

Syntactic Dependency in the First Half of the Twenty-First Century

Dependency representation in syntax used to be the staple diet of grammarians – since the Antiquity through the Middle Ages and up to modern times. But then, in the 1930s, Leonard Bloomfield introduced constituents to the English-speaking linguistic community, and the second half of the last century saw a genuine boom produced in and around C-approach by Chomskyan linguistics. Pushed into a corner of the linguistic stage, D-approach, however, not only survived, but almost immediately started taking back lost territories – slowly but steadily: Tesnière (1959), Lecerf (1960), Hays (1960, 1964), Mel'čuk (1962, 1963), Iordanskaja (1963), Robinson (1970), Kunze (1975), Mel'čuk (1988), Sgall and Panevová (1988/1989), etc. Several new linguistic frameworks where practically based on dependencies, even though this is not always explicitly stated, such as Case Grammar (Ch. Fillmore), Lexical-Functional Grammar (J. Bresnan), Relational Grammar (D. Perlmutter), Word Grammar (R. Hudson), or Cognitive Grammar (R. Langacker). In the first quarter of the twenty-first century, the position of D-approach in syntax seems to be rather strong. For a general review of main topics related to Synt-D, see Heringer (1993), Hudson (1993a,b), and Mel'čuk (2009); a description of German syntax in terms of Synt-D is offered in Engel (1977) and Heringer (1996), of English Syntax, in Mel'čuk and Pertsov (1987) and Apresjan et al. (1989), of Russian Syntax in Mel'čuk (1974) and Apresjan et al. (1992a, 2010). In Natural Language Processing, dependency syntax has

also been advanced by, for instance, Maxwell and Schubert (1989), Apresjan et al. (1992b, 2003). Nearly all state-of-the-art parsing proposals are today based on dependency: see Bohnet (2011) and the references therein. Furthermore, a significant number of corpora annotated with dependency structures are available (see the references in Burga et al. (2011). A good perspective on Synt-D in linguistics and Natural Language Processing is offered by Gerdes et al. (2011); more specifically, on Text Generation, see Wanner and Lareau (2009).

Acknowledgments

The ideas about linguistic dependencies presented in this article have been discussed more than once with and profited a lot from D. Beck, S. Kahane, and N. Pertsov; the final version of the text underwent the scrutiny of L. Iordanskaja, J. Milićević, L. Wanner, and R. Zangenfeind. I express my deepest gratitude to all of them for their fair criticisms and constructive suggestions.

Abstract

Dependency theory emerged in the 1960s in reaction to modernization theories of development, arguing that international inequalities were socially structured and that hierarchy is a central feature of the global system of societies. It sought to explicate the institutional structures by which powerful core states continued to exploit and dominate less powerful states even after decolonization and the establishment of official sovereignty in peripheral nations. Ignoring the core/periphery hierarchy is a mistake not only for reasons of completeness, but also because the ability of core capitalist states to exploit noncore resources and labor has been a major factor in deciding the winners of global competition. A key insight of dependency theory is that capitalist globalization has occurred in waves and that waves of integration are followed by periods of globalization backlash. Although industrial production has largely moved from the core to the noncore, rather than flattening the world this trend has been accompanied by the extension and reorganization of modes of control and exploitation based on financial transactions and foreign investment.

Dependency theory emerged out of Latin America in the 1960s in reaction to modernization theories of development. *Dependistas* attributed the difficulties of development in the global South to the legacies of the long history of colonialism as well as contemporary international power relations. This approach suggested that international inequalities were socially structured and that hierarchy is a central feature of the global system of societies. It was a reformulation of earlier theories of imperialism but it focused on the institutional structures by which powerful core states continued to exploit and dominate less powerful states even after decolonization and the establishment of official sovereignty in the noncore. It also focused on the continuing consequences of the global hierarchy for the development of national societies in Latin America (Cardoso and Faletto, 1979). This approach was eventually extended to Africa and Asia and it inspired the world-systems perspective.

In the 1970s, the world-systems perspective emerged out of dependency theory when Samir Amin, Andre Gunder Frank, and Immanuel Wallerstein began to formulate the concepts and to narrate the analytic history of the modern world system. A whole global system was conceived as a stratified structure composed of economically, culturally, and militarily dominant core societies (themselves in competition with one another) and dependent peripheral and semiperipheral regions. Some dependent regions have been successful in improving their positions in the larger core/periphery hierarchy, while most have simply maintained their peripheral or semiperipheral positions. This perspective on world history also examines certain cyclical features of social change and long-term patterns of development in historical and comparative perspective. The development of the modern world system is alleged to be driven primarily by capitalist accumulation and geopolitics in which businesses and states compete with one another for power and wealth. Competition among states and capitals is conditioned by the dynamics of struggle among classes and by the resistance of peripheral and semiperipheral peoples to domination and exploitation from the core. The contemporary semiperiphery is composed of large and powerful countries in the global South (e.g., Mexico, India, Indonesia, Brazil, China) as well as smaller countries that have intermediate levels of economic development (e.g., the East Asian NICs, South Africa, Israel).

Dependency theory requires that we think structurally. We must be able to abstract from the particularities of the game of musical chairs that constitutes uneven development in the system to see the structural continuities. The core/periphery hierarchy is reproduced, though some countries have moved up or down. The interstate system remains, though the internationalization of capital has further constrained the abilities of states to structure national economies. States have always been subjected to larger geopolitical and economic forces in the world system, and as is still the case, some have been more successful at exploiting opportunities and protecting themselves from liabilities than others.

Dependency theory emerged to contest modernization theory, which contended that development would diffuse from the developed to the underdeveloped societies by means of certain kinds of contact between the two. Andre Gunder Frank proposed the notion of "the development of underdevelopment" to explain how certain kinds of hierarchical interaction based on economic exploitation and neocolonial forms of political/military control continued to reproduce the inequalities between the developed and the less developed national societies. Other dependistas examined the conditions under which some developing societies were able to somewhat successfully overcome the larger structures of power–dependence relations and to develop core-like economies and polities. Cardoso and Faletto (1979) explored the notion of 'dependent development' and this notion was examined in the work of Peter Evans (1979, 1995). Other researchers used data on large numbers of national societies to test hypotheses about the effects of international dependence on national development and within-country inequality, often finding that the negative effects on development and the increasing of within-country inequality predicted by dependency theory were confirmed (e.g., Beer and Boswell, 2002).

From the perspective of dependency theory, many of the phenomena that have been called 'globalization' are the continuation of trends that have long existed. The expansion of international trade, financial flows, and foreign investment by transnational corporations and banks in recent decades are similar to the great nineteenth-century wave of globalization. Much of the globalization discourse assumes that until recently there were separate national societies and economies and that these have now been superseded by an expansion of international integration driven by information and transportation technologies. Rather than a wholly unique and new phenomenon, globalization is primarily international economic integration, and as such it is a feature of the world system that has been oscillating as well as increasing for centuries.

The Great Chartered Companies of the seventeenth century were already playing an important role in shaping the development of world regions. Certainly the transnational corporations of the present are much more important players, but the point is that 'foreign investment' is not an institution that only became important since 1970 (nor since World War II). Giovanni Arrighi (1994) has shown that finance capital has been a central component of the commanding heights of the world system since the fourteenth century. The current floods and ebbs of world money are typical of the late phase of very long 'systemic cycles of accumulation.'

Dependistas have long contended that ignoring the core/periphery hierarchy or treating the noncore as inert are grave mistakes, not only for reasons of completeness, but also because the ability of core capitalists and their states to exploit noncore resources and labor has been a major factor in deciding the winners of the competition among core contenders. Moreover, the resistance to exploitation and domination mounted by noncore peoples has played a powerful role in shaping the historical development of world orders for centuries. Thus, world history cannot be properly understood without attention to the continuities and changes in global power–dependency relations.

Phillip McMichael (2000) has studied the 'globalization project' – the abandoning of Keynesian models of national development and a new (or renewed) emphasis on deregulation and opening national commodity and financial markets to foreign trade and investment. This approach focuses on the political and ideological aspects of the recent wave of international integration. The term many prefer for this turn in global discourse is 'neo-liberalism' but it has also been called 'Reaganism/Thatcherism' and the 'Washington Consensus.' The worldwide decline of the political left predated the revolutions of 1989 and the demise of the Soviet Union, but it was certainly also accelerated by these events. The structural basis of the rise of the globalization project is the new level of integration reached by the global capitalist class. The internationalization of capital has long been an important part of the trend toward economic globalization, and there have been many claims to represent the general interests of business before. Indeed every modern hegemon has made this claim. But the real integration of the interests of capitalists all over the world has very likely reached a level greater than at the peak of the nineteenth-century wave of globalization.

Dependency theory has always been compatible with an analysis of the global class structure as a whole. Samir Amin's (1980) important study of the global class structure and the North/South wage gap that is far greater than differences in productivity is a valuable contribution that was made long before the global stage of capitalism school discovered the global class structure. But dependistas can agree that the transnational segments of both capitalists and workers have grown and become more important in both production and politics, and so the analysis of transnational class relations is more important than it has been in the past. Of course, the big question is whether or not this new level of transnational integration will be strong enough to prevent competition among states for world hegemony from turning into warfare, as it has always done in the past, during a period in which a hegemon (now the United States) is declining.

The insight that capitalist globalization has occurred in waves, and that these waves of integration are followed by periods of globalization backlash, has important implications for the future. Capitalist globalization increased both intranational and international inequalities in the nineteenth century and in the late twentieth and early twenty-first centuries within-country inequalities mostly increased, while between-country inequality has remained at the same high level that it attained in the nineteenth century (O'Rourke and Williamson, 2000; Bornschier, 2010). Dependency theorists note that industrial production has largely moved from the core to the noncore, but rather than flattening the world this has been accompanied by the extension and reorganization of modes of control and exploitation based on financial transactions and foreign investment. The economic rise of China and India has not much reduced by the overall amount of global inequality, especially if we take into account the growth of inequality within countries as well as between them.

Dependency theory is alive and well. Understanding the changing nature of global power is not a task whose time has ended. Penetrating the fog of globalization, including the rise of the BRICS and the rise of transnational social movements that are contesting the basic logic of capitalist accumulation, can be well understood only using the past insights of dependency theory and extending it to the present and the future.

Depression

Abstract

Depression, a term often used synonymously with being fed up or unhappy, is much more than this. It is a serious mental illness characterized by low mood, loss of interest or pleasure in nearly all activities, feelings of utter hopelessness, and can lead to suicide. It is currently ranked the third most prevalent moderate and severe disabling condition globally by the World Health Organization. This article explores the history of depression, diagnosis, etiology, evidenced-based management, and scales used in depression.

Introduction

> That's the thing about depression: A human being can survive almost anything, as long as she sees the end in sight. But depression is so insidious, and it compounds daily, that it's impossible to ever see the end. The fog is like a cage without a key.
>
> Elizabeth Wurtzel

Depression can mean different things to different people, which is why it is vital that one clarifies what they mean when taking a history from them. The word comes from the Latin 'deprimere' which translates as 'press down.' Indeed, many do describe it as a downward pressure, and 'feeling down' is colloquially used often. *The Oxford Dictionary* (2010) describes it as "a mental condition characterized by severe feelings of hopelessness and inadequacy, typically accompanied by a lack of energy and interest in life." However, one overall sentence does not do this complex and serious issue justice; depression has its own personal meaning for each individual suffering from it. Winston Churchill used to call it his 'Black Dog,' and I recall one individual describing his depression as a "mental and physical equivalent of walking through treacle, because everything is an effort and slowed down." One chapter in a book cannot also do it justice, but what follows is a brief overview of some important aspects of depression.

History of Depression

Depression was one of the earliest conceptualized mental health disorders. Hippocrates was the first physician to recognize melancholia, as he termed it, being a 'brain disorder' in the fifth century BC (Angst and Marneros, 2001). Despite this astute observation, the observation was superseded by the humoral theory, which held that it was caused by excessive black bile. Asclepiades, a first-century BC Greek physician, prescribed 'bathing, exercise, massages, and wine' to help with the mood disorder (Alexander and Selesnick, 1966). In the nineteenth century, French doctors started thinking of mania and depression as being on the same continuum: 'la folie double forme' (Baillarger, 1854). It was around this time that van Gogh produced his paintings, and future historians would comment on how they could tell when he was in his depressed stages of his illness from his paintings alone (see **Figure 1**). Note the use of dark colors in his palate in **Figure 1**, and the use of dark skies and black crows often interpreted as a reflection of his dark mood and suicidal thoughts. He shot himself in the wheat fields within a month of this painting. Others who advanced the knowledge and made significant contributions to the field included Kraepelin (the first disease model of psychiatry, and included social and psychological aspects), Freud, and Bleuler (Goodwin and Ghaemi, 2000). This ultimately culminated in the contemporary classifications given below.

Diagnosis (Signs and Symptoms) and Phenomenology

There are two widely recognized contemporary classification systems in use worldwide for depression: ICD-10 (WHO, 1992) and DSM-IV (APA, 1994), both of which have new versions due out in the near future.

A duration of at least 2 weeks of symptoms is required for the diagnosis. In ICD-10, depression is divided into a depressive episode (one) or depressive disorder (more than one), both having subcategories of mild, moderate, or severe. Severe episodes can be with or without psychosis. The difference between categories is a clinical judgment that depends on the number, type, and severity of symptoms present.

A diagnosis is made following an extensive history, obtaining collateral history from close family members and health care professionals where possible, possibly aided by rating tools (see below) and following careful exclusion of other disorders and illnesses that can be causing the problem. The other issues (differential diagnoses) that need to be screened for include:

- Substance abuse causing depressed mood (e.g., drugs and alcohol)
- Prescribed medications causing depressed mood (e.g., centrally acting antihypertensives, lipid-soluble beta blockers, benzodiazepines, and progesterone contraceptives)
- Medical illness causing depressed mood
- Medical illness presenting in a similar way to depression (e.g., hypothyroidism)
- Other psychiatric disorders: mania, hypomania, bipolar, schizoaffective, schizophrenia, and so on
- Bereavement unless symptoms persist for more than 2 months or show marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation (DSM-IV, APA, 1994).

Table 1 outlines the symptoms for both classification systems. The ICD-10 has ten symptoms compared to DSM-IV's nine symptoms for measuring the severity of depressive states.

Functional impact needs to be taken into account. Even with the above guidelines, assessing mood can be problematic, especially regarding the phenomenology of the terms used. Andrew Sims (1995), in what is often regarded as the definitive text on phenomenology, provides the following clarifications. "Feelings" are described as the "passive subjective experience of emotion … [they are] personal convictions, predictive forecasts and social sensibilities." They are the reaction to an experience and are transient, as opposed to 'affect,' which is 'differentiated specific feelings toward objects,' and 'mood,' which is the 'prolonged prevailing state.' 'Emotion' can be regarded as the physiological and psychosomatic concomitants of mood' (Sims, 1995). There is of course a huge variation in mood that is not pathological, and clinicians must make a collaborative judgment based on the information given to them, the classification given above, and the social impact, and the extent of the suffering. Clinicians can also make use of validated rating scales given in the following paragraphs.

Apathy, the absence of feeling or interest, and anhedonia, the inability of experiencing pleasure in previously enjoyed experiences, are common in depression. Anhedonia has been described as 'probably the best clinical marker predicting response to treatment (Sims, 1995). Many also experience depersonalization, which is where the thoughts and feelings seem unreal or not to belong to oneself.

There are critics to the diagnostic validity using the classification systems described, using both US and UK data (Kendler and Gardner, 1998; Wainwright et al., 1997), suggesting that the current systems are rather arbitrary, and should be replaced with a likelihood measurement on a continuum rather than a binary decision of whether someone is depressed or not.

In the UK, general practitioners and other primary health care professionals are urged to actively seek out depression in these individuals and others suspected of having depression using the two screening question test (if either are positive, confirmatory evidence should be sought):

1. During the last month have you often been bothered by feeling down, depressed, or hopeless?'
2. During the last month have you been bothered by having little interest or pleasure in doing things?'

For those with a chronic health problem you need to ask three further questions (NICE, 2009):

During the last month have you often been bothered by:

a. Feelings of worthlessness?
b. Poor concentration?
c. Thoughts of death?

In rare and severe cases, psychosis can occur in depression. The psychotic delusions usually take the form of what is known a 'nihilistic' delusion, where there is a belief that oneself, a part of one's body, or the real world does not exist or has been destroyed.

Etiology

There are several models of depression looking at the disorder from different perspectives. What follows is a brief overview of some of them.

Psychological and Behavioral

Aaron Beck in 1979 proposed a triad of thoughts that served as a cognitive theory for depression. The triad involves negative thoughts about:

- The self (i.e., the self is worthless)
- The world/environment (i.e., the world is unfair)
- The future (i.e., the future is hopeless)

The cognitive–behavioral model (CBT) is well established and has a wide evidence base for it (Whitfield and Williams, 2003). Indeed in the UK, it is recommended as the first-line approach for mild to moderate depression (NICE, 2009).

Negative automatic thoughts occur immediately in response to a situation or event, which are outside the person's control. CBT aims to work collaboratively with the current situation and attempts to generate alternative hypotheses and more logical explanations. Cognitive distortions are common (see **Figure 2**), and may stem from underlying 'core beliefs' or 'schemas.' These core beliefs can refer to the self-worth of an individual and take a negative form in depression (e.g., I am unlovable).

Some have expanded on this work and propose a 'five areas approach' (Williams, 2001) for categorizing the symptoms: the theory being that a change in any of the other four areas (social, cognition, behavioral, and social) can lead to a change in the fifth (mood).

Seligman's learned helplessness theory (1975) has been used to explain depression being caused by the perceived lack of control of a situation's outcome (such as abuse for example).

Psychodynamic

According to the self-discrepancy theory (Higgins, 1987), depression occurs when there is a consistent discrepancy between the ideal representation of the self, and the actual representation. This leads to hostility directed toward the actual self. Largely unconscious conflicts between the id (primal desires), superego (a mental representation of the rules and norms of society), and ego (that serves to bridge the other two) lead to regression, repression, and anger turned inward on the self. One needs to resolve early developmental and interpersonal conflicts to overcome depression.

Selective abstraction

Over-generalization

Social

Lack of good-quality social support (actual or perceived) is a risk factor for depressive relapse. Brown and Harris' (1978) often-quoted study found the following vulnerability factors for depression:

- Having three or more children under the age of 14 years
- Not working outside the home
- Lack of a confiding relationship
- Losing the mother before the age of 11 years

'Life events' which are major social events or changes for an individual are thought to play a part in depression. Holmes and Rahe (1967) 'score' life events by calculating 'life change units' that apply to events in the past year of an individual's life which are added, and the final score will give a rough estimate of how stress affects health (**Table 2**). One needs to bear in mind that the way someone responds to any life event can be perceived differently.

An example of a formulation for the social model of depression is given in **Figure 3**.

Genetic

The concordance rate for major depression is greater in monozygotic twins (46%) compared to dizygotic twins (20%) (McGuffin et al., 1996). Other authors think heritability is at about 40–50% for depression and probably more in severe depression (Levinson and Nichols, 2014). Those with first-degree relatives having major depression or recurrent depressive disorder (e.g., parent or sibling) have an increased risk of

developing depression, by up to five times (Levinson and Nichols, 2014).

Even though twice more females than males are thought to be developing depression, the inheritance of the disorder is thought to be from the combined action of several genes exerting a small or modest effect. Several genes are thought to play a role in developing depression. These genes confer a vulnerability to affective disorder, but the genes must interact with nongenetic (environmental) factors in order to precipitate the illness. This is the basis of the stress-vulnerability theory.

Hormones and Neurotransmitters

In depression, there are reports of a disturbed hypothalamic–pituitary–adrenal axis. Specifically, there appears to be a disrupted normal circadian rhythm of cortisol secretion. Elevated cortisol levels have been found in depressed individuals. Also the normal nocturnal rise in thyroid stimulating hormone (TSH) is blunted in depression.

Those with depression have been shown to have early morning wakening, a diurnal mood variation (usually worse in the mornings), and a short REM latency (which is the time from falling asleep to the onset of REM sleep). Melatonin may, therefore, have a part to play (Puri and Hall, 2004).

In 1965, Schildkraut discussed the monoamine hypothesis of mood disorders, suggesting there is a depletion of central monoamine in depression. The monoamines implicated include serotonin, norepinephrine, dopamine, glutamate, and brain-derived neurotrophic factors (Dunlop and Nemeroff, 2007). The following findings are in favor of the hypothesis: many antidepressant drugs work by increasing the availability of monoamine, such as tricyclic antidepressants (that increase the availability of monoamines in the synaptic cleft), monoamine oxidase inhibitors, and selective serotonin reuptake inhibitors (that increase the availability of serotonin). Also, reserpine, a drug that depletes monoamines such as serotonin, can lead to severe depression and suicide. Serotonin especially has been found to be reduced in depression and can be brought up to normal levels with treatment. However, evidence against the monoamine hypothesis includes that despite the antidepressants causing rapid biochemical changes as described, the clinical improvement observed only starts much later. Also not all drugs that increase the central availability of monoamines have an antidepressant effect (Puri and Hall, 2004). **Figure 4** depicts a neurobiological model of depression (Gelder et al., 2001).

Cultural

Pathological low mood can be defined differently in different cultures. The tools for diagnosis have mainly been developed in Europe or America. The prevalence across countries can, therefore, vary widely. The rates may be influenced by those seeking help too. For example, Punjabi women do not see depression as a medical condition requiring treatment, but

merely a normal reaction to life stressors (Bhugra et al., 1997). In China, many patients receive a diagnosis of 'neurasthenia,' that when reassessed using detailed tools, can be reclassified as major depression in over 80% of cases (Kleinman, 1982). It could be that the diagnosis of neurasthenia is made to avoid the stigma associated with a diagnosis of depression. In Japan, 'shinkei-suijaku' is treated with Morita therapy involving mandatory rest and isolation, followed by progressively more difficult work, and a resumption of a previous social role (Tsung-Yi Lin, 1989). From a study covering 14 countries worldwide, and using the General Health Questionnaire (described in the following section), the prevalence rates of depression varied widely from 1.6% in Nagasaki, to 26.3% in Santiago. The highest levels of correlation were found in symptoms of feeling guilty or worthless, and the lowest correlations were on the biological symptoms of sleep disturbance and altered appetite (Simon et al., 2002).

Treatment and Management

The following is largely based on the current National Institute for Health and Clinical Excellence (NICE) guidelines in the UK for people over 18 years with depression (NICE, 2009). NICE provides national guidance and advice to improve health and social care, and the recommendations are based on the best available evidence, also taking into account the cost–benefit ratio. **Table 3** depicts the stepped-care model for treating depression (NICE, 2009).

For those on step 2, subthreshold depression means fewer than five symptoms from the DSM-IV criteria above. Also, for this group, sleep hygiene is recommended. This essentially includes establishing regular sleep and wake times, avoiding excess eating, smoking, or drinking alcohol before sleep, creating a proper environment for sleep, and taking regular physical exercise. Clinicians are advised to offer active monitoring (to discuss concerns, provide information about depression, reassess within 2 weeks, and to contact the person if they do not attend follow-up appointment). The low-intensity psychological and psychosocial interventions referred to include individual self-help based on CBT principles, computerized CBT, group CBT, and group physical activity programs. Antidepressants are not routinely advised in this group because the risk–benefit ratio is poor, unless they have a past history of moderate–severe depression or they present with subthreshold symptoms that have been present for 2 years or more, or they have subthreshold symptoms for less than 2 years but they do not respond to other interventions.

Herbal remedies such as St John's wort are not recommended by NICE (2009) due to the lack of standard dosage and there are potentially quite serious interactions with other drugs such as oral contraceptives, anticoagulants, and anticonvulsants.

For those on step 3 (**Table 2** above) the recommended management is medication (usually SSRI), high-intensity psychological interventions (e.g., CBT, interpersonal therapy,

Focus of the intervention	*Nature of the intervention*
STEP 4: Severe and complex depression; risk to life; severe self-neglect	Medication, high-intensity psychological interventions, electroconvulsive therapy, crisis service, combined treatments, multiprofessional and inpatient care
STEP 3: Persistent subthreshold depressive symptoms or mild to moderate depression with inadequate response to initial interventions; moderate and severe depression	Medication, high-intensity psychological interventions, combined treatments, collaborative care, and referral for further assessment and interventions
STEP 2: Persistent subthreshold depressive symptoms; mild to moderate depression	Low-intensity psychosocial interventions, psychological interventions, medication, and referral for further assessment and interventions

behavioral couples therapy if relationship contributing to or maintaining depression, or partner can be therapeutically treated), or combined treatment (antidepressants and psychological intervention, e.g., CBT).

For those with severe and complex depression the focus there is on maintaining a safe environment and combined, often multifaceted interventions are required, including medication, high-intensity psychological interventions, electro convulsive therapy, crisis service, and inpatient care. Suicidal ideation and risk assessments should be carried out at every stage and consultation.

There is another chapter devoted to pharmacotherapy for depression and, therefore, it is not covered further here.

Scales Used in Depression

The Beck Depression Inventory (BDI) is a 21-question self-report inventory and is one of the most widely used tools for assessing and screening depression severity (Beck et al., 1961). It looks at both mental and somatic components of depression, but has as its drawback the same problems as any other self-reported tool.

The Hospital Anxiety and Depression Scale (HADS) is a 14-item scale; seven of the items relate to anxiety and seven relate to depression (Zigmond and Snaith, 1983). Each item on the questionnaire is given a score from 0 to 3, and this means that a person can score between 0 and 21 for either anxiety or depression. The items that relate to depression are:

- I still enjoy the things I used to enjoy
- I can laugh and see the funny side of things
- I feel cheerful
- I feel as if I am slowed down
- I have lost interest in my appearance
- I look forward with enjoyment to things
- I can enjoy a good book or radio or TV program

The shortened version of the Patient Health Questionnaire (PHQ-4) is just as good as the longer PHQ9 or HADS or BDI for those who have previously had depression (Thapar et al., 2014).

PHQ-4 involves four questions: "Over the last 2 weeks how often have you been bothered by the following problems: Feeling nervous, anxious, or on edge? Not being able to stop or control worrying? Little interest or pleasure in doing things? Feeling down, depressed, or hopeless?"

For each question, there are four answers: not at all (score 0), several days (score one), more than half the days (score two), and nearly every day (score three). The maximum score is 12. Scores can be interpreted using the following cutoffs: score 0–2 = normal, score 3–5 = mild, score 6–8 = moderate, score 9–12 = severe.

Suicide

Most people (90%) who commit suicide have a psychiatric disorder, and of these 50% have depression (in Puri and Hall, 2004). People who commit suicide are more likely to be:

- Male
- Elderly
- Suffered loss or bereavement
- Unemployed
- Retired
- Childless
- Living alone in a densely populated town
- Broken home in childhood
- Mental or physical illness
- Loss of role
- Drug and alcohol misuse
- Social disorganization, including overcrowding and criminality.

Protective factors against suicide include:

- Religious devoutness
- Lots of children
- Times of war

The above list is taken from Puri and Hall (2004).

During any risk assessment, certain features of a suicide attempt would indicate a higher degree of suicidal intent. These would include whether there was any planning of the event, if the person did not seek help afterward, whether precautions were taken to avoid discovery, whether any dangerous method was used, and the presence of a will or a suicide note.

The National Confidential Inquiry, which produces annual reports on suicide and homicide in the UK, reported in 2014 that particularly the first 3 months after discharge remain a time of high suicide risk – this is especially true in the first 1–2 weeks, and the most common method for suicide remains by hanging (National Confidential Inquiry Annual Report, 2014).

Availability and access to items that can be used for suicide make a difference. Several occupations with the highest suicide rates (per 100 000 population) during 1979–80 and 1982–83, including veterinarians (ranked first), pharmacists (fourth), dentists (sixth), doctors (tenth), and farmers (thirteenth), have easy occupational access to a method of suicide such as pharmaceuticals or guns (Roberts et al., 2013). Literature reviews suggest gun availability increases the rates of suicide in the USA (Miller and Hemmingway, 1999, 2001). More recently, the high-risk occupations appear to have changed, and a breakdown of the 10 highest risk occupations for suicide for men and women is given in **Table 4** below (from Roberts et al., 2013).

Prognosis

With appropriate treatment, 70–80% of individuals with major depressive disorder can achieve a significant reduction in symptoms (Halverson and Bienenfield, 2014). For mild depression, spontaneous recovery is likely. For major depression, four out of five who have had psychiatric care for an episode will have at least one more episode in their lifetimes (with a median of four episodes). The average length of an episode of depression is 6–8 months (NICE, 2013), but the outlook obviously varies with the severity of the episode.

The risk factors for increased risk of depression recurrence include (Timonen and Liukkonen, 2008):

- Three or more episodes of major depression
- High prior frequency of recurrence

Table 4 Suicide rates ranked by occupation

Summary

Depression is the most common psychiatric disorder, and has a huge impact in the sufferer as well as for those close to him or her. It is ranked the third most prevalent moderate and severe disabling condition globally by the World Health Organization, and with time, this is predicted to worsen, to a ranking of second leading cause of disease burden by 2020 (WHO, 2004). It is clear that more funding and resources are needed to tackle a problem that affects so many people across the world, especially when treatment strategies are available and effective. It could literally be a case of life or death.

Abstract

Depression is a syndrome involving sadness and doubt, loss of motivation, and the ability to experience enjoyment. Pessimism (the negative pole of the optimism dimension) is a trait consisting of the generalized expectancy of bad outcomes in important life domains; the term hopelessness conveys a similar sense of anticipating bad outcomes. All these characteristics have been implicated as contributors to adverse health outcomes. Pessimism has been related to low persistence at health promotion efforts and to activities that reflect disengagement from life. Pessimism has also been linked to adverse reactions in certain medical events (e.g., coronary artery bypass surgery, heart transplantation) and to cardiovascular disease. Depression has long been related to elevated likelihood of subsequent cardiac death after initial myocardial infarction, and to heart disease more generally. Both pessimism and depression have also been linked to inflammation, which may be a precursor to several health problems. There is evidence that some of these effects are larger among younger than older persons. Future research must focus more on the pathways by which these variables create their influence.

Depression is a psychological syndrome encompassing a variety of symptoms, including loss of energy and motivation; loss of the capacity to experience happiness or enjoyment; feelings of sadness, despair, and hopelessness; and sometimes a sense of guilt, shame, or worthlessness. Depression is a debilitating problem in its own right for people who experience it. Depression can also have serious adverse implications for physical health and well-being.

Depression is an episodic condition. After first manifestation it can be long-lasting or repeated, but it does not usually last for the person's entire lifetime. On the other hand, there are also personality traits that have strong overtones of depression. Consider the trait dimension of optimism versus pessimism. Optimists are people who expect good things to happen to them; pessimists expect bad things to happen. Pessimism thus resembles aspects of depression. Unlike depression, however, pessimism is an enduring trait. The dimension of optimism versus pessimism has been studied a good deal in Health Psychology. Some of that research has found that this aspect of personality also relates to physical well-being.

The concept of hopelessness has links to both depression and pessimism. Sometimes hopelessness is used to refer to a state and sometimes it is used to refer to a personality trait. One might view the concept of hopelessness as a conceptual bridge between the (usually temporary) state of depression and longer lasting traits such as pessimism. People experiencing depression often feel hopeless about the future; people who are pessimistic are more broadly and consistently lacking in hope for the future.

This article describes some of the research that links depression and pessimism to health problems. As background to that research, the next section describes a conceptual basis for the hypothesis that these variables may be involved in health.

Pessimism, Hopelessness, and Disengagement

The concepts of optimism and pessimism are rooted in centuries of folk wisdom about effects of people's expectations for the future. Scientific research on optimism and pessimism also is rooted in the principle of expectations for the future. By taking expectancies as a starting point, this research makes a connection to more than a century of psychological theory (Carver et al., 2010; Carver and Scheier, 2014). That is, the expectancy construct relates to a broad collection of theories of motivation and action called expectancy–value theories. This body of theory suggests a basis for examining how the traits of optimism and pessimism are expressed in motivation, behavior, and feelings. These various expressions of optimism and pessimism turn out to also represent a set of potential pathways by which this personality disposition may relate to health.

Expectancy–value models begin with the idea that behavior is aimed at attaining desired goals (values). Without a valued goal, there is no reason to act. People also have varying degrees of confidence or doubt about being able to attain the goal. Without confidence, again there will be no action. Only with sufficient confidence do people exert efforts and remain engaged in those efforts. These principles pertain to specific values and focused confidence, and they also apply to the more general traits of optimism and pessimism. In optimism and pessimism the 'confidence' involved is simply broader in scope.

These expectancy–value principles provide the basis for many predictions about optimists and pessimists. When confronting a challenge, optimists should be confident and persistent, even if progress is difficult or slow. Pessimists should be more doubtful and hesitant. This divergence should be further amplified under conditions of adversity. Optimists are likely to believe that the adversity can be handled successfully, whereas pessimists are likely to anticipate disaster. These differences in orientation can lead to differences in behavioral persistence, differences in efforts to take precautions, differences in many decisions and actions that pertain to health risks.

People's behavioral responses to adversity are important, but overt behavior is not the only response that occurs when people confront adversity. People also experience emotions in such situations. Difficulties elicit a mixture of feelings, and variables such as optimism influence the balance among the

feelings. Again, predictions are easily derived from theory. Optimists expect good outcomes, even when things are difficult. This confidence should yield a more positive mix of feelings, for example, enthusiasm, excitement, and challenge. Pessimists expect bad outcomes. This is related to more negative feelings, such as anxiety, sadness, or despair. There is good evidence for such emotional differences between optimists and pessimists (Carver et al., 2010; Segerstrom, 2006).

The experiences of intense distress, anxiety, hopelessness, and despair have physical concomitants, including changes in the neuroendocrine and cardiovascular systems. There is some evidence to suggest that these physiological changes play an important role in health outcomes, although research on the precise pathways of influence is at an early stage. Such processes may influence a person's probability of getting a disease in the first place, they may influence the progression of diseases, and they may even influence mortality. There is a good deal of evidence that personality differences in optimism versus pessimism relate to differences in health-related outcomes (Rasmussen et al., 2009).

As stated earlier, depression has conceptual connections to pessimism, that is, a sense of negativity about the future. This negativity about the future means that the reasoning just outlined about expectancy–value theories also applies to the syndrome of depression. Depression should be associated with relative lack of persistence in trying to maintain health, and it should also be associated with the sorts of physiological responses to challenges and adversity that pessimism is associated with. The result in each case should be a potential for adverse influences on health.

Pessimism and Health

Health is a complex phenomenon with many contributors (for a broader discussion see Carver and Vargas, 2011). Health is partly a matter of the presence versus absence of disease. Health is partly ensuring that your body is in a condition that will help it fight off any potential intruders. Health stems partly from engaging in health-promoting activities and avoiding health-damaging activities. Health also comes partly from not having intense and potentially damaging physiological arousal states too often and for too prolonged a period. There thus are several ways in which either traits such as pessimism or states such as depression can influence health.

Pessimism and Health-Related Actions

Sometimes being persistent in goal-related efforts is an important determinant of health and well-being. This would be the case when persistence is expressed as active efforts at health promotion, that is, to be proactive in staying healthy. A reasonable hypothesis is that optimists, who are confident about attaining and maintaining the goal of good health, should be more likely than pessimists to continue the active pursuit of health-promoting activities. Evidence from several studies supports this hypothesis.

One study looking at potential individual differences in health promotion followed a group of heart patients who were involved in a cardiac rehabilitation program (Shepperd et al., 1996). Optimism among participants was related to increases in exercise levels across the study period. Optimism also related to greater success in lowering levels of saturated fat, lowering body fat, and lowering an index of global coronary risk.

Another study followed coronary artery bypass patients during the period immediately after surgery (Scheier et al., 1989) and reexamined them 5 years later (described in Scheier and Carver, 1992). The early part of the project focused mostly on patients' responses to the surgery as an event in their lives; the later part of the project investigated their lifestyles 5 years postsurgery. In the early part of the project, optimists gave several indications of focusing on getting back on their feet quickly. They were viewed by the hospital staff as recuperating faster, and they reported concentrating on the rehabilitation process. Pessimists, in contrast, were more likely to be avoiding even thinking about the future. Five years later, optimists were more likely than pessimists to be taking vitamins, to be eating low-fat lunches, and to be enrolled in a cardiac rehabilitation program. Thus, both initially and later on, pessimists were less persistent than optimists in a wide range of health-promoting behaviors.

Another health risk that is related to behavior, though in a different manner, is HIV infection. Infection can occur from engaging in sexual activities with partners who are not known to be disease free. By taking steps to avoid such sexual practices – for example, avoiding sex with unknown partners – people reduce their risk of infection. One study of HIV-negative gay men found that optimists reported having fewer anonymous partners than pessimists (Taylor et al., 1992). This finding suggests that optimists were making efforts to reduce their risk, thereby safeguarding their health.

Another example comes from a study of hospital employees at risk for skin cancer (Friedman et al., 1995). Optimists were significantly more likely than pessimists to report the intentions to engage in skin cancer-relevant health prevention behaviors (e.g., regular sunscreen use). In addition, among those identified at screening as having suspicious lesions, those who were more optimistic were also more likely to comply with recommended follow-up care.

Other studies have examined health-related habits reported by groups of people with no particular salient health concerns. At least two such projects found that optimists reported more health-promoting behaviors than did pessimists (Robbins et al., 1991; Steptoe et al., 1994). In sum, these results suggest that optimism is associated with behaviors aimed at promoting health and well-being and reducing health risk.

It is important to note, however, that while optimists definitely do not stick their heads in the sand and ignore threats to their well-being, neither do they always jump immediately into action. Rather, they display a pattern of attending to risks selectively, reacting to risks that are clearly applicable to them and also are related to potentially serious health problems (Aspinwall and Brunhart, 1996). If the potential problem is minor, or if it is unlikely to bear on them personally, they do not display elevated vigilance. This fits the idea that optimists scan their surroundings for threats to their well-being, but save their active coping efforts for threats that are truly meaningful.

Pessimism and Disengagement

The hypothesis discussed in the preceding section derives from the idea that optimism leads to continued effort and pessimism leads to giving up. In that section the focus was on the continued effort. What about the giving up? Several kinds of health-relevant behaviors seem to reflect a giving up tendency. One of them is alcohol consumption, which at high levels is a health risk. Excessive alcohol consumption is often seen as occurring in the service of an escape from one's problems. If so, it seems reasonable that pessimists should be more vulnerable to alcohol abuse than optimists.

Results from at least two studies fit this picture. One study of women with family history of alcoholism found that pessimists were more likely than optimists to report drinking problems (Ohannessian et al., 1993). Another study (Strack et al., 1987) examined people who had already been treated for alcoholism and were now entering an aftercare program. This study found that pessimists were more likely to drop out of the aftercare program and to return to drinking than optimists. These two studies converge in showing that pessimists display a form of disengagement – alcohol consumption – more than optimists.

People can give up in many ways, of course. Alcohol dulls awareness of failures and problems. People can also turn their backs on their problems by distracting themselves. Even sleeping can help people escape from situations they do not want to face. Sometimes, though, giving up is more complete. Sometimes people give up not just on specific goals, but on all the goals that define their lives, by killing themselves. Pessimism has been found in several studies to be a key indicator of suicide risk (Beck et al., 1985; Fawcett et al., 1987; Petrie and Chamberlain, 1983).

Physiological Reactivity and Disease Susceptibility

The examples just described all concern how people varied in their efforts to protect themselves against health risks, or how hard they tried to maintain good health, or the extent to which they engaged in behaviors that may reflect a disengagement from such efforts. Such factors are important contributors to disease susceptibility. That is, people who take steps to avoid health risks will generally be healthier in the long run than people who do not. But there are also more direct associations, cases in which people's susceptibility to diseases is not so much a function of their overt actions as it is of their body's autonomic reactions.

This pathway to disease follows from overuse of the body's normal reactions to stress. Many kinds of experiences produce involuntary physiological changes. Although these changes are generally functional and adaptive in the short run, some of them can also disrupt important health-protective functions. In such cases, a person's stress and coping processes affect physiological reactions in a way that can render the person more vulnerable to promotion or progression of disease. This is particularly likely to be the case if the stress reaction is prolonged or repeated.

This sort of effect is generally assumed to begin with the experience of emotional distress. Intense emotional states are associated with a variety of cardiovascular responses and neuroendocrine and immune changes. Given the broad array of responses that are associated with negative emotions, there again are diverse specific potential influences on health. Some of them follow from cardiovascular responses per se, others follow from endocrine responses.

As described earlier, optimists and pessimists differ in the patterning of emotions they experience when confronting adversity. This means that – given identical experiences – they should experience different degrees and durations of physiological changes that in the long run can create problems. An example of a study that seems to support this notion was reported by Räikkönen et al. (1999). This study examined associations of pessimism with blood pressure elevations. This study involved 3 days of ambulatory monitoring of blood pressure during normal activities. Results indicated that pessimists were more likely to have elevations in blood pressure during those activities than optimists. This study does not provide evidence of disease per se, but it suggests that further examination of the role of pessimism in the development of hypertension is warranted.

The role of stress on neuroendocrine and immune functioning has been extensively examined in recent decades. Research shows that psychological stress can lead to dysregulation of the neuroendocrine system (i.e., disruption of typical ranges of regulation) both through direct physiological pathways and also through behavioral changes intended to aid in survival (Tsigos and Chrousos, 2002). Stress and dysregulated neuroendocrine functioning can also prompt immune responses, which may result in an increase in inflammation (Chrousos, 1995). Elevated inflammation is an important predictor of heart disease and several other disorders (Cesari et al., 2003; Dentino et al., 1999; Luc et al., 2003; Miller et al., 2002).

As people who are more pessimistic may experience more psychological stress, with greater feelings of anxiety, sadness, or despair, it follows that pessimistic people may also have higher circulating markers of inflammation. One large-scale study looked at over 5000 men and women from the Multi-Ethnic Study of Atherosclerosis, all of whom were confirmed to have no history of clinical cardiovascular disease at initial measurement. Nonetheless, pessimism was associated with higher levels of several key markers of inflammation (Roy et al., 2010).

It is hard to study initial vulnerability to disease, because doing so requires recruiting participants who are all completely healthy, and waiting until some of them become ill. An alternative strategy is to recruit persons who are all in the same category of risk for a disease, or are at the same early stage of a disease, and following them over time. One study that used that strategy examined women's carotid intima-media thickness (Matthews et al., 2004). Carotid intima-media thickness is an index of atherosclerosis in the carotid artery, a physical marker of the development of heart disease. In this study, intima-media thickness was measured among middle-aged women at baseline and again 3 years later. Greater pessimism at the initial assessment predicted increases in intima-media thickness at follow-up. Optimists experienced almost no increase over the 3-year period.

A good deal of research has examined differences in well-being that follow the initial diagnosis or treatment of disease. Some of this work looks at responses to medical procedures.

For example, the study of men undergoing coronary bypass surgery (described a little earlier) by Scheier et al. (1989) included measures of the patients' progress through the surgery itself. Two kinds of indirect evidence suggested that pessimists fared more poorly than optimists even on the operating table. Specifically, pessimists were more likely to display two markers during surgery that are widely taken as indicators of myocardial infarction (MI). Thus, pessimists may have been at greater physical risk during the bypass surgery itself.

Scheier et al. (1999) collected data on a second sample of bypass patients. The first analyses of data from that project focused on a problem that often arises after major surgery: the need for rehospitalization, due either to infection from the surgery or to complications from the disease underlying the surgery. Scheier et al. (1999) found that optimistic persons were significantly less likely to be rehospitalized either for problems related to postsurgical infection or for problems related to the coronary artery disease, even after controlling for medical variables and other personality measures.

Another research group has explored how positive expectations before heart transplant surgery related to later medical adherence and health (Leedham et al., 1995). In this case, optimism was assessed at several levels of abstraction. Patients completed measures of optimism prior to surgery; they were then evaluated at discharge and at 3 and 6 months postsurgery. Initial scales assessed patients' confidence about the efficacy of treatment, their expectations about their future health and survival, and broader expectations for the future. Confidence about the future predicted better adherence to the postoperative medical regimen, and strongly predicted nurses' ratings of the patients' physical health at 6 months after surgery. There was also a tendency for positive expectations to predict longer delays before development of infection (a near-universal side effect of heart transplantation).

Perhaps the most compelling study to date on optimism and cardiovascular disease grew out of the Women's Health Initiative, a large-scale project designed to study changes in and predictors of quality of life, chronic disease, morbidity, and mortality among women across America. Using participants in this project, Tindale et al. (2009) studied over 95 000 women across an 8-year period. All of the women were free of cancer and cardiovascular disease at study entry. The results were clear and striking. Optimists were less likely than pessimists to develop coronary heart disease (CHD) and to die from CHD-related causes, and had lower total mortality due to all causes, across the 8 years of study. The advantage due to optimism ranged from 9% for incident cases of CHD to 30% for CHD-related mortality.

Associations between Depression and Health Outcomes

Most of the foregoing has dealt with pessimism or hopelessness. What about depression and health? Links between depression and adverse health outcomes have been examined extensively in recent years (Lustman et al., 2000; Rutledge et al., 2006; Seifert et al., 2012). There is, of course, a great deal of evidence that depression follows from adverse health events. Depression also cooccurs with a variety of serious medical conditions of widely varying types (e.g., Freedland et al., 2003; Gavard et al., 1993; Kessler et al., 2008; Minden and Schiffer, 1990; Thombs et al., 2006; Sadovnick et al., 1996). In most of these cases, of course, the depression is most readily interpreted as a reaction to the physical illness, rather than a contributor. But that does not mean that depression is therefore unimportant to illness.

Again, there appear to be both behavioral and medical pathways to poorer health. Recall that one consequence of pessimism is less effort and persistence in health-promoting behaviors. The same is true for depression. Increased depressive symptoms often result in poorer self-care, including missed medical appointments and failure to take medicines as prescribed. Depression has also been linked to a variety of behaviors indicating an unhealthy lifestyle, such as physical inactivity, poor diet, and elevations in use of tobacco (Bonnet et al., 2005; Steptoe et al., 1997).

Depressive symptoms can also be a barrier to self-care behaviors aimed at repairing damage already done. For example, Anda et al. (1990) noted that depressive symptoms were negatively related to the ability to quit smoking over a 9-year period. A large meta-analysis found a substantial relationship between depression and medical noncompliance (DiMatteo et al., 2000). Thus, some proportion of the poorer health among depressed persons may be attributed to simply not following the doctor's orders.

These failures of adequate self-care can create disease-specific outcomes such as poor glycemic control in diabetes (Bane et al., 2006; Lustman et al., 2000), and a more general vulnerability to whatever challenges are represented by the illness. Thus, depression can act through behavioral mechanisms to make an existing illness worse.

Links between depression and subsequent health are best documented for cardiac-related events. For example, Ladwig et al. (1991) gathered psychological data from over 500 male survivors of MIs shortly after the MI, including a measure of depression. By 6-month follow-up, 12 patients had died from new cardiac events. Death was predicted by post-MI depression.

Stronger findings relating depression to post-MI mortality were reported by Frasure-Smith et al. (1993). Depression was assessed by interview during the week after an MI. In addition, a large number of medical variables were collected. By 6 months after the initial interview, 12 cardiac-related deaths had occurred, and depression was a significant predictor. Patients meeting criteria for clinical depression after their MI were five times more likely than nondepressed patients to have died by the 6-month follow-up.

Frasure-Smith et al. (1999) have more recently reported a larger and longer term study of men and women who had been hospitalized for MI. Both men and women who were depressed while in the hospital were three times as likely to die of cardiac causes than were patients who were not depressed.

It is tempting to view this evidence as reflecting physical manifestations of a loss of desire to continue living. Perhaps the depressed MI patients in the studies reviewed above simply gave up the struggle to go on. This would represent a kind of disengagement response, albeit one that is quite different from the overt actions represented by suicide or alcohol abuse.

Depressive symptoms that emerge after the onset of physical illness generally reflect the stress of adapting to the illness.

In some cases, though, the disease itself may induce depression by physiological pathways. For example, approximately half of persons with multiple sclerosis (MS) experience at least one major depressive episode (Minden and Schiffer, 1990; Sadovnick et al., 1996). Structural brain changes due to the MS activity contribute to the development of the depressive symptoms (Pujol et al., 1997; Bakshi et al., 2000). Here is a case in which effects go both ways. That is, in one study reductions in depression by psychotherapy led to reductions in MS-related disability and fatigue (Mohr et al., 2007).

It is no surprise that depression can follow from illness. But evidence suggests that depression can exacerbate the illness. Indeed, recent research suggests that depression can be an independent risk factor for the initial development of certain kinds of disease. The best evidence for relationships of this kind is in cardiovascular disease. One meta-analysis of 11 longitudinal studies revealed that clinical depression predicts the subsequent development of CHD in initially healthy people (Rugulies, 2002). Depressive symptoms also increase the risk of ischemic stroke (Majed et al., 2012). Depression appears to be a stronger risk factor for mortality in patients with CHD than it is for the general population (Barth et al., 2004). Indeed, Rozanski et al. (2005) noted that depression is as strong an independent predictor of cardiac events as are traditional risk factors such as high blood pressure and tobacco use.

Several cross-sectional studies have found that depressed persons have elevated levels of inflammatory markers that themselves are predictive of developing cardiovascular disease (Cesari et al., 2003; Dentino et al., 1999; Luc et al., 2003; Miller et al., 2002). More recently, depressive symptoms were found to lead to inflammation in healthy adults (Stewart et al., 2009) and in healthy adolescents (Copeland et al., 2012). These findings suggest that inflammation may be a pathway by which depression fosters development of cardiovascular disease independent of other traditional risk factors, and that the pathway develops throughout adolescence. It is important to note that these studies examined samples of healthy individuals rather than those already diagnosed with cardiovascular disease.

A meta-analysis of studies on depression and type 2 diabetes found that depression is also associated with a 60% increased risk of type 2 diabetes (Mezuk et al., 2008). Given the role of inflammation in insulin resistance (Shoelson et al., 2006), this raises questions about whether these inflammatory mechanisms may contribute to relationships between depression and health outcomes in a variety of other medical conditions.

Potential Moderators

The focus of this article has been on the direct associations between health and the psychological variables of depression and pessimism. However, some attention should also be paid to limitations on – or moderators of – such effects. One limitation may be the seriousness of the disease. It is possible that the effects of the psychological variables under discussion (and others) are greater among persons with disease that is less severe than among persons whose disease is advanced. That is, perhaps advancing disease affords less opportunity for psychological variables to gain leverage over the impact of the disease.

Another potential moderator is the age of the person whose health is under study. In one earlier review of the literature, Scheier and Bridges (1995) noted that variables such as personality and depression sometimes had stronger influences on health among younger than older persons. Indeed, every age difference they encountered was one in which stronger associations between personality and health outcome occurred among younger persons. This observation led Scheier and Bridges to suggest that biological factors may become more important in determining disease outcomes as people grow older, and psychological factors correspondingly less important.

Closing Comment

This article reviewed some associations that have been observed between pessimism, depression, and health. Evidence of associations between these psychological variables and health is fairly robust. On the other hand, it would be wrong to conclude that the mechanisms underlying these effects are well understood. In some cases the mechanism is obvious: persisting in a health-promoting exercise activity, taking steps to control one's weight, acting to lower one's health risks – all these are behavioral ways in which optimism and hopefulness can enhance health outcomes through overt behavior. In other cases, though, the mechanism is far more speculative, involving potential neuroendocrine and immune responses as mediators. The role of such mediators is presently under active investigation, but there remain many uncertainties. Despite the many questions remaining, though, the pattern seems consistent with a picture in which continued optimistic engagement with life goals promotes better health outcomes, and in which the loss of such engagement – giving up – promotes poorer outcomes.

Deprivation: Relative

Abstract

The theory of relative deprivation aims at accounting for puzzling phenomena. Why, when agents belong to a group in which promotion or social mobility is scarce, they are more satisfied than those who belong to a group where promotion or social mobility is more frequent? Why inequality is more easily tolerated in a society where it is greater than in another? The theory was extended to explain social movements and revolution.

Following Runciman (1966), we can "roughly say that A is relatively deprived of X when (1) he does not have X, (2) he sees some other person or persons, who may include himself at some previous or expected time, as having X (whether or not this is or will be in fact the case), (3) he wants X, and (4) he sees it as feasible that he should have X." Relative deprivation and the notions that are directly or indirectly linked to it constitute a strongly structured conceptual set, what Merton terms a 'middle range theory,' that is, a set of propositions that combines hypotheses and empirical regularities proper to a specific domain of validity and without which these regularities would be neither accounted for nor cemented.

The concept of relative deprivation was first used by Stouffer et al. (1949) in *The American Soldier*. However, this idea can be found in the writings of several classical sociologists such as Tocqueville (1852), Durkheim (1893, 1897), and Weber (1904). It also features in the works of contemporary nonsociologists such as Duesenberry (1949) and Easterlin (1973). These authors underscore the importance of the notion of relative income compared to absolute income and thereby that of the comparison between two statuses of the same individual at two different time intervals. This accounts for certain paradoxical phenomena that the standard economic theory is unable to explain. Starting with the well-known study of Stouffer et al. (1949), the theory of relative deprivation has been gradually developed, particularly by Merton and Kitt (1950), Runciman (1966), Boudon (1977), and Hirschman (1981). Its application expands to various areas, mostly to those where the relations between individual contributions and retributions are crucial, just like the problems of justice and equity or revolution. This theory is also interpreted from different standpoints that are discussed later.

Themes and Theory of Deprivation

Relative deprivation is often used in *The American Soldier* to account for puzzling results whose exhaustive study was conducted by Merton and Kitt (1950). One of these results is that the most favored groups seem to be inclined to criticize the system of promotion. Thus, Military Police soldiers belonging to a unit where promotion is scarce are satisfied with the promotion system governing their military career. In contrast, men in the Air Corps, although belonging to a body where promotion is frequent, are dissatisfied with their opportunities for promotion. To explain this paradox, Stouffer et al. (1949) introduced the notions of relative deprivation and reference group: "if at the same age, level of education, and seniority, the majority of my colleagues and I have been promoted, I will consider my promotion as normal. If, however, I have not been promoted, I will go through a feeling of injustice, which can translate into criticism of the mobility system. If the promotion is relatively scarce in the group to which I belong or refer to in my evaluations, I will be very pleased with my promotion. However, if I am not promoted I will not experience any sense of injustice since all my peers have not been promoted." Deprivation therefore occurs only under specific conditions:

1. The individual retains some knowledge of the system of social promotion, mobility, or retributions.
2. He/she does not get an expected good, for example, promotion.
3. This expectation is based on an evaluation and a comparison that the individual conducts between his/her position, contributions, and retributions on the one hand, and those of a large number of his/her peers, who make up his/her reference group on the other. This condition expresses inter alia the principle of interdependence among social actors.
4. He/she has a feeling of inequity, which translates into criticism of the mobility system.

Thanks to particular models illustrating the idea of deprivation, several heterogeneous paradoxical phenomena have been accounted for by the founders of sociology as well as by contemporary sociologists. As explained and formalized by Cherkaoui (2005), Tocqueville (1852) underscores the following surprising positive ecological correlation: The higher the economic prosperity, the quicker the laws of the old regime disappear and political liberalization gains ground in certain regions, the stronger the support of these regions to the revolution. He points out that: "While prosperity (…) in France is growing, general attitudes seem to be less content and more anxious; public dissatisfaction is turning sour; hatred for all the old institutions is increasing. The nation is clearly heading towards a revolution. Moreover, the parts of France which should have been the major sources of this revolution are precisely those parts where progress is being shown most…. It is not always by going from bad to worse that we fall into revolution."

Durkheim (1893, 1897) also develops two partly complementary ideas linked to deprivation. In the *Division of Labor*, he maintains that happiness is not an increasing monotonic function of wealth. The relation between satisfaction and abundance

 http://dx.doi.org/10.1016/B978-0-08-097086-8.32039-6

of wealth is a parabolic function with a maximum corresponding, according to him, to the happy medium, to the *aurea mediocritas* of the common saying: "happiness lies between the two extremes of wealth." Besides, the French sociologist devotes the chapter on 'the division of constrained labor' of the same book to the analysis of the relation between deprivation resulting from the violation of meritocratic rules and the questioning of social order. Equal opportunities and congruence between distribution of talents and jobs are, in his view, the conditions of legitimacy and stability of social order. In *Suicide*, it is the pure model of anomie that expresses deprivation. When aspirations and expectations grow faster than the means of realization and when these are not set back or brought to an end, a state of anomie occurs with numerous individual and social consequences. The absence of social regulation is a source of social pathology. With no clear limits to the legitimate needs, and free from any social pressure, men like Goethe's Faust will experience the infinite dimension of desire, frustration, and torment and can go as far as committing suicide.

Hirschman (1981), as an example of contemporary authors, explains tolerance to inequality in the developing countries by his 'tunnel effect', which is directly tied to the theory of deprivation and reference group. Let us take the example of a car driver in a two-lane tunnel with two lanes going in the same direction. Suppose that, after a short period of time during which no car in either lane has moved forward, the cars on the other lane start moving. He will feel relieved and hopeful that the cars on his lane will also move forward. However, upon realizing that only the cars on the other lane keep moving, he will feel disappointed and later furious. He might end up tempted to readjust the inflicted injustice by switching to the other lane, thus violating traffic regulations. The same applies to inequalities. An improvement of the social positions of my neighbors or my peers gives me hope. In case of disappointment, I will feel deprived and try to change the order of things.

Generating Mechanisms of Deprivation

One can wonder, following Boudon (1977), if all these phenomena are not likely to be generated by social mechanisms. He sets up simple models stemming from game theory, which bring about and explain relative deprivation. In his view, this deprivation can be interpreted as the product of the structures of interaction in which individuals end up. Deprivation entails the notion of competition for good and that of objective opportunities for promotion (Stouffer et al., 1949).

Let us suppose a group of N players who can win the lot B1 for a stake C1 or the lot B2 for the stake C2 with

$$\mathrm{B1} > \mathrm{C1},\ \mathrm{B2} > \mathrm{C2},\ \mathrm{B1} > \mathrm{B2},\ \mathrm{C1} > \mathrm{C2},\ \mathrm{B1}\ \text{and}$$
$$\mathrm{C1} > 0,\ \mathrm{B2}\ \text{and}\ \mathrm{C} > 0$$

$n1$ and $n2$ are the number of winners of the lots B1 and B2, respectively, with $n1 + n2 = N$.

Being rational, the players will bet on C1 rather than C2 if the expected net profit by betting on C1 is superior to that corresponding to C2.

If $x1$ players ($n1 < x1 < N$) bet on C1, the expectation of net profit E1 ($x1$) of a player betting on C1 is

$$\begin{aligned}\mathrm{E1}(x1) &= (\mathrm{B1} - \mathrm{C1})n1/x1 + (\mathrm{B2} - \mathrm{C2})(x1 - n1)/x1 \\ &= (\mathrm{B1} - \mathrm{B2})n1/x1 + \mathrm{B2} - \mathrm{C1}\end{aligned}$$

On the other hand, the expectation of net profit E2 of a player betting on C2, when $x1$ ($>n1$) players bet on C1 is,

$$\mathrm{E2}(x1) = \mathrm{B2} - \mathrm{C2}$$

Thus, $x1(>n1)$ players bet on C1, a player is advised to bet on C1 rather C2 if

$$\mathrm{E1}(x1) > \mathrm{E2}(x1)\ \text{or}\ (\mathrm{B1} - \mathrm{B2})n1/x1 + \mathrm{B2} - \mathrm{C1} > \mathrm{B2} - \mathrm{C2}$$

that is,

$$(\mathrm{B1} - \mathrm{B2})/(\mathrm{C1} - \mathrm{C2}) > x1/n1$$

One can analyze the relationship between the game structure and deprivation, which is the proportion of individuals betting on C1 (the highest price) but winning only B2 (the lowest price). For that matter, one should examine the different values of the ratio (B1 – B2)/(C1 – C2) that is the ratio of the possible additional gain and the additional cost on one hand, the percentages of players 100 $x1/N$ and of the winners 100 $n1/N$ on the other hand.

The simulation shows how complex the nature of relations is between deprivation and the objective opportunities of promotion. Let us consider the following general cases:

1. The rate of deprivation increases with the values (B1 – B2)/(C1 – C2). This rate increases with the marginal rate of profitability or return on investment {(B – B2) – (C1 – C2)}/(C1 – C2), as shown by Kosaka (1986) and Yamaguchi (1998) who systematize the propositions of Boudon (1977) and deduce new ones, and make 'critical points' emerge.
2. The highest levels of deprivation correspond to cases where a small number of players win the lot B1, the highest one.
3. Deprivation rate is moderated as long as the moderated value lots are distributed to players in a limited number (the case of the Military Police in Stouffer's study). This is no longer the case when the number of winners increases (the case of men of the Air Corps).
4. We get equal deprivation rates when only a small number of players win important lots or when a large number of players win less important ones.
5. In general, the curves corresponding to identical relative deprivation levels are complex with different plateaus (ceilings) and critical points.

The simulation confirms the idea according to which the game structure determines the deprived players and their number. It is equally possible to simulate the situations in which the players are not equal, that is, when the group is stratified and each social class has its different resources and behaviors toward risk. These simple game models particularly show the conditions in which the mere fact of increasing everyone's promotion opportunities can result in further increasing promotion expectations. These modes also demonstrate that the propositions of Tocqueville, Durkheim, and Stouffer are not unconditionally valid: when equal opportunities increase

among individuals, deprivation tends to grow under certain conditions, but it can decrease under others. The trend of the relation between promotion and social mobility depends on the structure of interdependence among individuals.

Manzo (2009, 2011) enriches our understanding of relative deprivation by two new proposals. First, he suggests introducing a distinction between relative deprivation frequency, that is, the proportion of agents who do not have what they want, and relative deprivation intensity, that is, the strength of the feeling agents associate with this discrepancy. The distinction suggests that different mechanisms generate these two proprieties. Second, he carries on agent-based simulation by introducing a new component. He analyses the level of satisfaction of the agent by taking into account neighborhood based interindividual comparisons. The model with interpersonal comparisons that inversely link individual dissatisfaction and the diffusion of deprivation situation leads to two paradoxically apparent propositions: 'more opportunities, more dissatisfied yet less intensely dissatisfied agents' and 'more opportunities, fewer dissatisfied yet more intensely dissatisfied agents.'

Deprivation and Collective Violence: A Case Study

Revolution theorists generally agree on the assumption that revolutions occur during a period of economic growth and political liberalization. This paradox seems to cast doubt on the hypothesis of the rationality of human behavior. One can wonder why people revolt at the very moment of prosperity. Deprivation theorists respond that an improvement in objective living conditions tends to generate higher expectations. As the expectations grow faster than the improvement in objective conditions, a wider gap comes up and translates into a higher degree of deprivation. This model is similar to the Durkheimian theory of anomie, as shown by Besnard (1987) and Coleman (1990). The revolution theory developed particularly by Davies (1962) and Gurr (1968) is different. In their view, revolutions occur when a long period of socioeconomic prosperity is immediately followed by a sudden downturn that is a sharp decrease in gratification accompanied by a constant increase in expectations. The rapidly widening gap between expectations and gratification generates revolution. This proposition commonly translates in an inverted J curve.

Even though the notion of deprivation in this theory is not as precisely and explicitly defined as with Stouffer, it is easy to demonstrate that it also supposes a meaningful difference deems unacceptable between the expectation and the realization at the individual level and an interpersonal comparison. First, with regard to intrapersonal comparison, the difference is at the same time relative and absolute. It is absolute if at the $t1$ moment we compare expectation with realization. It is relative if at the $t2$ moment, the difference between expectation and realization deems unacceptable or unbearable compared to what it was at the $t1$ moment. Besides, individuals with threatened social positions or subject to downward social mobility compare themselves to those with stable positions or upward mobility.

Several varieties of deprivations can be constructed. The first one relies on the theory of relative deprivation and shows up in the works of Gurr (1968) particularly for whom "a psychological variable, relative deprivation, is the basic precondition for civil strife of any kind, and that the more widespread and intense deprivation is among members of a population, the greater the magnitude of strife in one or another form." The relation between deprivation and civil strife is, however, mediated by societal variables such as coercive potential that can deter strife, institutionalization (social and political association may provide nonviolent means for expressing discontent), facilitation (i.e., means that facilitate civil strife), and finally legitimacy of the regime.

The second variety is that of the status inconsistency that can be found in the founding fathers works such as those of Tocqueville (1852) and Weber (1904, 1924), and in such contemporary research as that of Lenski (1954). The rich bourgeois and the well-off farmer, who, thanks to the liberalization of the rules governing the acquisition of land, end up as owners of vast lands, remain for the French aristocrat mere plebeians carrying visible stigma of their original social class. If, as Tocqueville states, the bourgeois and the aristocrats become unknown to each other, it is mainly because they evaluate each other according to values located on different scales. The bourgeoisie has economic quasi monopoly and looks forward to assuming political power and enjoying honors, whereas the bourgeoisie cannot gain access to these institutions because the noblesse get in the way. The bourgeoisie feels compelled to opt for the revolutionary solution. Conversely, in the nineteenth century, as Weber points out, while the Prussian Junker maintains his monopoly over the army and the bureaucracy, the industrialists buy lands to acquire nobility titles and gain access to political positions. Politically, as Weber states, this type of industrialist is reactionary. These two examples illustrate two special cases of the multiple effects of the status inconsistency whose complete taxonomy Cherkaoui (1995) attempts to construct.

The collective action theorists, especially those of mobilization, question the theory of revolution based on deprivation. As revolution is a collective action seeking to realize a public interest, the rational actor will face problems specific to this type of action, particularly the temptation of free riding. Following Olson (1965), it is believed that the rational individual belonging to a latent group as a social class seeking to satisfy collective goals would rather turn to see the sacrifices accepted by others. He would not be interested in participating in a revolutionary enterprise whose costs can be heavy. Eventually, as pointed out by several analysts of revolutionary movements as Cochin (1924) and Brinton (1965), the revolutions are the product of some elites of organized and almost unanimous conspirers toppling weak governments at periods of social disorganization. For the theorists of mobilization and social movements as Oberschall (1973) and Tilly (1978), a psychological explanation of the revolutionary phenomenon is unable to account for the shift from disenchantment to the mobilization against authorities and in particular against the state. Besides, the theory of rational choice reduces the moral and solidarity incentives, which play a key role in the emergence of collective action. This is sometimes a moral obligation for the individual who belongs to collectivities where solidarity bonds are predominant. From this perspective, it is rather the lack of participation that will be costly. Oberschall shows that the lack of bonds and the dismantling of social networks are major setbacks to mobilization. Cherkaoui (2007, 2013) has recently

tested this theory in his studies on social movements in Morocco and on the Arab spring uprisings by taking into consideration other central variables such as the legitimacy of governing power, the homogeneity and solidarity of elites, and the role of the army.

However, by trying to turn the theory of relative deprivation into a maid of all work, it is put through risks that hang over any theory whose domain of application has been excessively expanded. But despite some criticism, its underlying principles remain solid. To mention but one, the principle of interdependence is the center of its axiomatic structure that the formalization put forward by Boudon and others has clearly highlighted. To explain and understand, inter alia, the inflationary spiral of demands, the perception of inequality, the individual conception of justice and of equity, or the degree of satisfaction, the theory of relative deprivation reminds us of an obvious fact that the sociological tradition has taken for granted since the days of Montesquieu (1748) whereby the structures of interdependence between social actors are often decisive.

Abstract

Desegregation is a process through which members of formerly separated groups are brought together, often through the removal of institutional barriers to interaction. Two recurring arguments have been presented in favor of desegregation. The first holds that the process promotes intergroup harmony and tolerance; the second holds that it promotes social justice and equality. Present in the earliest work in the field, these arguments continue to set the agenda for future research, inspiring recent debates, developments, and controversies.

Introduction

Desegregation is a deceptively simple concept. It can be defined as a process through which members of formerly separated groups are brought together, often through the removal of formal barriers to interaction. The concept acquired historical significance largely through its association with political movements such as the Civil Rights Movement in the United States and the antiapartheid movement in South Africa, which, among other goals, fought for the abolition of legal systems of racial segregation.

A simple definition of desegregation belies its complexity however. Desegregation is generally not best conceived as a discrete *event*: it is more typically an unfolding and incomplete *process* that takes multiple forms and operates across multiple spatial and temporal scales. In the United States, for example, the phrase 'educational desegregation' denotes a wide range of processes, including the abolition of Jim Crow laws, open enrollment in formerly exclusive schools or colleges, quota systems, bussing programs, the realignment of district school boundaries, and the establishment of 'magnet schools' in African-American neighborhoods. Writing this article is challenging because these different forms of desegregation are associated with different historical trajectories, lived experiences, and social consequences. Moreover, educational desegregation is itself distinct from residential or employment desegregation, which are in turn distinct from the desegregation of spaces of leisure, recreation, or public facilities.

Our aims in this article, then, must be modest. We do not pretend to offer a systematic review of the complex literature that has addressed the varying forms of segregation. Instead, we sketch a few wider themes, issues, and debates in the field emphasizing, in particular, how desegregation affects the social psychology of relations between groups. Much of the work we discuss has been conducted in the United States and has focused on racial segregation, and this emphasis reflects a wider bias in the historical development of the field. We focus on two recurring arguments in favor of desegregation. The first holds that desegregation is essential to the promotion of intergroup harmony and tolerance; the second holds that desegregation is essential to the struggle for social justice and equality. As we discuss in our conclusion, these arguments continue to set the agenda for future research, inspiring recent debates and controversies. They were present too in the earliest work in the field.

The Early Social Science Case for Desegregation

In order to understand the emerging social science case for desegregation, we need first to understand what it was directed against, namely the assumption that the separation of 'races' is a social, political, or even natural imperative. Nightingale (2006) holds that a number of 'transnational' arguments in favor of race segregation were predominant in the late-nineteenth and the early twentieth centuries, gaining both scientific credibility and popular appeal. One suggested that different 'races' were naturally adapted to different environments and indeed that those environments were intimately related to their characteristics. Livingstone (1991) has shown, for example, how geographers at this time believed that place, climate, and group morality were intimately connected. The torrid equatorial regions, they argued, had fostered a 'lower' race of Africans distinguished by their sensuous, spontaneous, emotional, and childlike character, while Europeans could thank their more temperate environments for their virtues of reason, restraint, thrift, and endeavor. Each race had its proper place in the world to which it was adapted and from which its moral character had arisen. As such, the entry of one group into the environment of another was deemed inherently dangerous, as personified by the figure of the colonist who had 'gone native.' However anachronistic this line of argument seems now, it was taken seriously at the time. (Read, for example, Nightingale's (1996) account of the measures taken by the British Army to prevent their soldiers succumbing to the degenerative effects of the Indian summer.)

A second argument in favor of segregation is perhaps more familiar, for it lingers as a residual explanation even in societies where *de jure* segregation has been abolished. It holds that contact between members of different ethnic and racial groups produces negative consequences. Along with the 'threat' of miscegenation, such contact creates friction between groups, arising as a result of cultural, intellectual, and moral differences, as well as instinctive aggressions. Such friction can in

 http://dx.doi.org/10.1016/B978-0-08-097086-8.24055-5

turn produce intergroup conflict that destabilizes society. In the early years of the twentieth century, in a period Pettigrew (2008) brands the 'nadir' of social science research on race relations, this kind of argument found support, among other sources, from the psychological literature on race differences in intelligence.

As the century unfolded, such arguments lost favor. Social scientists set about the task of 'puncturing the biological myths of race' (Fairchild and Gurin, 1978), and in what Samelson (1978) called an 'abrupt reversal,' racial inequality and conflict were attributed increasingly to the prejudices of the advantaged rather than the inferiorities of the disadvantaged. Desegregation emerged as a potential solution to range of ethnic and racial 'problems,' and many social scientists became political advocates within a struggle that was to ramify across the globe. In the United States, a cradle of this emerging vision, the social science case for desegregation was encapsulated by a contrast between two legal landmarks. If the 'Plessy versus Ferguson Ruling of 1896' had upheld the legal status of 'separate but equal' racial segregation of public facilities in the antebellum southern states and other parts of the United States, then the 'Brown versus the Board of Education Ruling of 1954' famously overturned this decision and set in motion a process that culminated in the end of *de jure* segregation in the United States.

Although their contribution has been much debated, that social scientists played a significant part in the *Brown* judgment is indisputable, as the outpouring of work that accompanied its 50-year anniversary reaffirmed (e.g., see the special issue edited by Pickren, 2004). Handing down their judgment on the legality of educational segregation, the Justices echoed the language of a statement prepared for the courts by a team of experts that included Isidor Chein, Stuart Cook, and Kenneth B. Clark (Since this landmark statement, several further Amicus Curae on the effects of segregation have been submitted to courts. For a recent example, see Grutter et al., Brief of the American Psychological Association as Amicus Curiae. http://www.apa.org/about/offices/ogc/amicus/grutter.pdf. Retrieved 24.11.13.). This statement argued that black children subjected to legal segregation would suffer a range of negative consequences, including self-hatred, reduced ambitions, 'defeatist attitudes,' and weaker educational aspirations and achievements. Conversely, white children 'benefiting' from such segregation were likely to acquire an unrealistic sense of personal worth, guilt feelings associated with their unfair advantage, and misplaced fears and hatreds of minority groups. Regarding relations between groups, the statement noted in addition that "Segregation leads to a blockage in the communication and interaction between the two groups. Such blockages tend to increase mutual suspicion, distrust, and hostility" (Clark et al., 1952/2004: p. 497).

Clark (1953) developed this emerging social science case in a landmark paper published in the *Journal of Social Issues*. Entitled 'Desegregation: an appraisal of the evidence,' the paper elaborated a model of social change that challenged the received wisdom that desegregation was dangerous policy that, if implemented, would lead to widespread conflict. The latter view, he argued, relied upon an outdated, pseudopsychology that presupposed that racial prejudices are so emotionally deep-seated, so intractable, that they inevitably thwart interventions to promote change. Clark insisted that the available evidence supported the opposite view. Desegregation could proceed smoothly, efficiently, and without violent resistance if implemented under the right conditions. Challenging the more cautious, 'gradualist' model of change recommended by some commentators (e.g., Ashmore, 1954), Clark proposed a sweeping transformation of American society. Desegregation should be implemented rapidly, decisively, and with the full weight of institutional sanctions against those who resist. Stateways could change folkways, and in due course, their associated patterns of racial attitudes would fall in line.

Of the early evidence supporting this argument, troops' reactions to the desegregation of the US armed forces during the Second World War is perhaps the most poignant. This evidence focused on the experiences of white soldiers brought together with their 'Negro' counterparts in order to fight in a war in which many of them would die. Desegregation in this context happened suddenly, with no questions asked, and as a matter of military expediency rather than for some noble ideal such as 'racial equality.'

Consider, for example, Star et al.'s (1949/1958) mixed-methods study of white soldiers' responses to the amalgamation of Negro platoons in infantry companies. Their quantitative survey demonstrated how the concrete experience of desegregation actually increased rather than decreased soldiers' support for its basic principles. Most infantrymen who had experience of soldiering in mixed platoons, for example, were either broadly accepting or positively supportive of further amalgamation with 'Negro' platoons (around 60%) and few (<5%) reported that they would actively 'dislike' this outcome. By contrast, most infantrymen soldiering in segregated platoons (>60%) reported they would actively dislike the desegregation of platoons and vanishingly few (around 2%) said they would like this process. Desegregation, in short, seemed to produce tolerant acceptance rather than resentful conflict, a process clarified by the interview accounts Star et al. (1949) gathered:

> Relations are very good. They have had their pictures taken together, go to church services, movies, play ball together. For a time there in combat our platoons got so small that we had to put a white squad in the colored platoon. You might think that wouldn't work well, but it did. The white squad didn't want to leave the platoon. I've never seen anything like it.
>
> Company Commander from Nevada; Star et al., 1949: p. 600

> When I heard about it, I said that I'd be damned if I'd wear the same shoulder patch they did. After the first day when we saw how they fought, I changed my mind. They're just like any of the other boys to us.
>
> Platoon Sergeant from South Carolina, 1949: p. 598

As these accounts illustrate, desegregation does not inevitably lead to more negative racial attitudes. Indeed, the opposite often proves true. Desegregation may improve ethnic, racial, and other intergroup attitudes by allowing participants to get to know one another better, form bonds of emotional affiliation and attachment, and even create a sense of shared

identity, as captured in the phrase, 'they are just like any of the other boys to us.' Later developed as 'the contact hypothesis,' this idea was to become a dominant theme in desegregation research.

Desegregation and the Reduction of Prejudice

In the conclusion of their paper, Star and colleagues voiced a note of caution. Researchers should be wary, they warned, of generalizing their findings to other types of intergroup relations. "Far from being a 'test case' in ordinary Negro-white relations, the combat setting may be regarded as a special case for making good relationships, for the sense of common danger and common obligation was high, the need for unity was at a maximum, and there was great consciousness of shared experience of an intensely emotional kind" (Star et al., 1949/1958: p. 600). They noted that these 'special' circumstances not only increase the likelihood of interracial contact having positive effects, but also promote what Gaertner and Dovidio (2000) would later term 'common identification.'

In his classic statement of the 'contact hypothesis,' which consolidated earlier work in the field (e.g., McKenzie, 1948), Gordon Allport (1954) was similarly cautious. He observed that desegregation can produce various consequences and that its nature and surrounding context was crucial. Indeed, paradoxically, contact may either worsen or improve relations between formerly segregated groups. If contact is superficial, marked by competition, of unequal status, or lacking institutional support, then it may perpetuate negative stereotypes and feelings about members of another group. However, if contact is intimate, cooperative, of equal status, and supported by institutional norms and structures, then it may reduce prejudice and dampen the potential for future intergroup conflict. Allport's classic statement of the contact hypothesis, then, was not a naive call for more interaction between groups, but a measured statement of the conditions under which such interaction yields positive outcomes.

In the intervening years since the publication of Allport's seminal work, many hundreds of studies have been conducted on the contact hypothesis. There is now a vast literature on how, when, and why contact is effective. Early reviews (e.g., Amir, 1969) of this burgeoning literature were no more than cautiously optimistic. Recent reviews present a far more confident picture of the field's contribution from which we wish to extract four themes (see Pettigrew and Tropp, 2006, 2011; Brown and Hewstone, 2005; Dovidio et al., 2003).

First, most research has confirmed that contact correlates negatively with prejudice. The average strength of this effect is modest ($r = 0.22$), but it emerges consistently across different historical periods, types of intergroup relations, and outcome measures. Early research focused mainly on race relations unfolding under conditions of institutional desegregation in domains such as housing (e.g., Wilner et al., 1952), employment (e.g., McKenzie, 1948), and education (e.g., Mann, 1959). Later work has encompassed a far wider array of social relations, including relations between Catholics and Protestants (Schmid et al., 2008), Arabs and Jews (Maoz, 2011), gays and heterosexuals (Herek and Capitanio, 1996), students and people with HIV/Aids (Werth and Lord, 1992), Dutch people and Muslims (Savelkoul et al., 2011), doctors and patients (Revenson, 1989), the young and the elderly (Caspi, 1984), and people with and without mental illness (Desforges et al., 1991). More exotic entries in the contact literature include work on attitudes toward divorcees, transvestite comedians, and nude sunbathers (Ray, 1983; Schiappa et al., 2005).

Second, although the majority of research has focused on the effects of contact on intergroup attitudes of the historically advantaged (Perhaps because the prejudices of the dominant group members have historically been perceived as the main problem in issues such as racism, the attitudes of the disadvantaged have often been neglected in the literature.), several studies have confirmed that contact also works in the opposite direction, reducing the 'prejudices' of the disadvantaged. For example, in postapartheid South Africa, positive contact with white South Africans has been associated with a range of attitudinal shifts among black South Africans, including reductions in negative emotions and social distance and increases in forgiveness and support for reconciliation (e.g., Gibson, 2004; Swart et al., 2011; Dixon et al., 2010). Even in the society that implemented 'the highest stage of white supremacy' (Cell, 1982), contact is softening the hearts and minds of the disadvantaged.

Third, the theoretical mechanisms through which contact produces positive effects have been progressively clarified. Early work tended to describe rather than explain such effects or to fall back on the simplistic assumption that contact dispels false stereotypes by providing participants with more accurate information about one another. Since the 1980s, building on advances in work on social categorization and identification, researchers have explored the role of cognitive processes such as decategorization (Miller and Brewer, 1984), mutual differentiation (Hewstone and Brown, 1986), and common identification (Gaertner et al., 1996) in mediating contact effects, treating such processes as either competing or sometimes as complementary explanations (e.g., see Pettigrew, 1998). For example, the common identity model holds that positive contact promotes a 'recategorization' process through which 'us' and 'them' become viewed as 'we' and that this cognitive shift then produces associated improvements in intergroup attitudes (e.g., Gaertner et al., 1989). More recently, researchers have also emphasized the role of affective processes in explaining the impacts of contact on prejudice. As **Figure 1** below illustrates – taken from Pettigrew and Tropp's (2008: p. 928) recent analysis of European survey data – the roles of anxiety reduction and empathy promotion have been attributed particular importance.

Fourth, emerging research suggests that contact works not only directly, via immediate face-to-face interactions between members of historically divided groups, but also indirectly, via social networks of connection, vicarious observation, mass-mediated communication, or even 'imagined' interactions. The so-called extended contact effect, for instance, indicates that being embedded in a diverse social network (i.e., having friends who have friends of another group) can in itself be sufficient to produce positive attitude changes. Originally posited by Wright et al. (1997), this idea has gathered momentum in recent years (Dovidio et al., 2011). Along similar lines, several recent studies suggest that

Figure 1 Path model of mediation of the contact–prejudice association by anxiety reduction and empathy. Reproduced from Pettigrew, T.F., Tropp, L.R., 2008. How does intergroup contact reduce prejudice? Meta-analytic tests of three mediators. European Journal of Social Psychology 38, 922–934.

simply imagining having an encounter with a member of another group improves our attitudes toward that group (Crisp and Turner, 2009), especially if participants also imagine that the encounter is happening under cooperative conditions (Kuchenbrandt et al., 2013).

In our opinion, this recent proliferation of work on indirect and imagined forms of contact exemplifies a broader shift of emphasis in the literature on intergroup contact and desegregation. There has been a gradual move away from research on how to promote sociopolitical and institutional change in real world settings and toward a more contextually abstracted study of prejudice reduction as an ideal in its own right (Durrheim and Dixon, forthcoming). Certainly, work on 'imagined contact' is at best tenuously connected to Clark and colleagues' original project, which sought to understand the conditions under which desegregation can become an effective mechanism of social change.

Desegregation and Social Justice

That project, it is worth reminding ourselves, was never simply about getting black kids to sit next to white kids in the classroom. It was never simply about getting members of different groups to hold nicer thoughts and warmer feelings about one another. Rather, it was a political project that sought to dismantle the forms of inequality that racial segregation had created. Dreger (1985) reminds us of what was at stake here and why desegregation was seen as such a vital a mechanism of sociopolitical change:

> Desegregation, led by school desegregation, has revolutionized the South. Let me describe what segregation was like when I came to the South in 1949. A black gas station attendant could pour the gas, but the white man who supervised the black attendant handled the money. There were *no* black cashiers in grocery stores, except in stores in deep black neighborhoods and even in the latter white owners or managers were constantly supervising closely. There were *no* black salespersons in major or even minor stores. There were *no* black bus drivers except for rickety buses devoted entirely to transporting black workers. There were some black school bus drivers for buses that carried black children. At the bus station, blacks stood back as whites got on first; if there was no room left, too bad. At the bus stops, blacks cleverly made it appear that they were occupied with other things in order to make it seem that they preferred to get on after whites. And of course, all the obvious marks were there, seats in the back of the bus, seats in the theater galleries, rear door entrances to white homes or establishments, and so forth …

> p. 124–125

The 'obvious marks' referred to here are, of course, the marks of subordination. They are the marks of a system of inequality that pervaded even the most banal scenes of everyday life, such as queuing for a bus, going to the cinema, or buying groceries, and acted as a constant reminder of one's place in the world. Early social science researchers were concerned fundamentally with the material and social psychological effects of this system on historically disadvantaged communities. They conceived desegregation as a vehicle of social justice and not only, or even primarily, as a vehicle of social harmony.

Evidence from research on the racial (re)organization of institutions of education and residence attest to the continuing importance of this political project. In the next section, we take the relationship between residential organization and social justice as an example. Readers interested in related work on educational desegregation can weigh the diverse perspectives offered by Orfield and Lee (2005), Schofield and Eurich-Fulcer (2001), and Rossell et al. (2002).

The (re)organization of residential space: Clark's (1965) classic the *Dark Ghetto* revealed the power of urban segregation not only to divide the disadvantaged from the advantaged, but also to divide them from the material resources and opportunities with which to build better lives, including education, employment, bank loans, and prospects for social mobility. Confined to poor, inner city neighborhoods, he argued, black residents also became trapped in a cycle of deprivation and indignity: "… the dark ghetto's invisible walls have been erected by the white society, by those who have power, both to confine those who have no power and to perpetuate their powerlessness" (p. 11).

It is largely because of this intimate relationship to poverty and exclusion that residential (de)segregation remains of such vital significance. Indeed, the organization of residential space has been described as a 'structural lynchpin' of race relations in the United States (Pettigrew, 1979) and elsewhere (Durrheim and Dixon, 2005). It is thus widely viewed as a *sine qua non* unlocking other forms of desegregation. *Ceteris paribus*, the 'dark ghetto' can be read as an analogy for urban relations between historically advantaged and disadvantaged groups in many societies.

In the decades since *the Dark Ghetto* was published a lot has changed in the United States. Partly because of the civil rights movement, many of the practices that helped to sustain urban segregation have now been outlawed by legislation such as the Fair Housing Act (1968) and the Equal Credit Opportunity Act (1974); it is now illegal, for example, for bankers or realtors to engage in practices of the so-called 'redlining' (e.g., refusing mortgages to clients who live in predominantly minority neighborhoods or channeling property purchases or lets along

racial lines). As the last century came to an end, there were also signs that some American cities were becoming less segregated or at least that 'hypersegregated' cities (Massey and Denton, 1988) might be downgraded to merely 'segregated.' It became possible to speak of 'stable racially integrated communities' (Ellen, 1998, 2000) who had not succumbed to the 'white flight' and resegregation, but instead established spaces of diversity. Certainly, there is sufficient variation – both within and between American cities – to enable systematic comparative work on the consequences of living in more or less racially diverse neighborhoods. This work confirms how and why desegregation remains a matter of social justice.

Consider, for example, **Figure 2** below, which depicts the racial demography of Chicago using an innovative technique in which different colored dots are used to represent members of different race groups living in different areas of the city (see Rankin, 2009). This kind of visual representation has the advantage of capturing the gradients and blurred boundaries between racially differentiated areas; the spaces of mixing and transition as well as the sharp territorial divisions. It thus provides a more subtle image of the nature of segregation than the standard modes of visual representation (e.g., see the inset image in **Figure 1**). Nevertheless, **Figure 1** also shows why Chicago is a city that regularly tops the segregation league table of American cities in what remains, unfortunately, a highly competitive field. It illustrates *in extremis* a pattern that is repeated in many other cities, as captured by Farley et al.'s (1978) memorable phrase 'Chocolate city, vanilla suburbs.'

Figure 2 Mapping residential distribution by race in Chicago, 2000. Taken from Rankin, B., 2009. http://www.radicalcartography.net/index.html?chicagodots (retrieved 20.10.13.). Note each dot represents 25 residents who self-identified as white, black, Hispanic, Asian, or other.

African-American residents, Hispanic, and other minority group residents are clustered mainly in the central city and immediately surrounding areas. The wider suburbs are overwhelming populated by white residents. In Chicago, this pattern has further ossified into a racialized division between northern and the southern parts of the city: the 'southside' having a high concentration of African-American residents, the 'northside' having very few.

Figure 3 provides another representation of Chicago, which displays the relationship between variations in racial demography of the city and household income. As is apparent, areas with a higher proportion of African-American residents tend to have lower average-income levels. This pattern is most prominent in the central areas of the city, where segregation and poverty starkly coincide. However, what does this kind of association mean? Is it coincidence, a historical artifact, the product of a 'third variable' such as class or cultural preferences? If not, does poverty lead to segregation or vice versa?

In the early 1990s, Douglas Massey and Nancy Denton (1993) addressed these kinds of questions in a book provocatively entitled 'American Apartheid.' This book presented compelling new evidence on the role of segregated environments in creating an African-American 'underclass' who had effectively become trapped in the self-same cycle of deprivation described by Clark some 30 years earlier. It showed that segregation served as an active cause and not merely a passive reflection of inner city poverty and that, above and beyond dynamics of class, race played a role *sui generis* in this

process. It showed that African-American segregation is maintained largely through institutionalized practices of discrimination in housing and mortgage markets, which effectively prevents upwardly mobile blacks from moving to wealthier, more racially integrated, neighborhoods. It showed, too, how in periods of economic recession problems such as unemployment often became concentrated within – indeed sometimes confined to – such communities, with often devastating social and economic consequences. Above all, it showed that dismantling urban segregation was a necessary component of for any meaningful policy of social change.

American Apartheid reinvigorated a tradition of research that had become somewhat moribund in period between the 1960s and the late-1980s. It brought questions about the relationship between urban segregation, desegregation, and social justice back into razor-sharp focus. Since its publication, there has been an explosion of work on the deleterious consequences of living in racially segregated environments or, to put the matter more positively, on the benefits of living in more diverse environments. Renewed interest in the links between race, residential organization, and poverty (e.g., Charles, 2001; Massey and Fischer, 2000) has been complemented by work on closely related problems. We want to extract two examples from a more complex and sobering literature.

The first example concerns the effects of racial diversity and segregation on the physical well-being of members of disadvantaged groups. Growing evidence indicates that living in more diverse communities is literally good for your health. Relative to living in segregated environments, it leads to decreases in infant mortality, increases in longevity, and general improvements on other indicators of physical and mental well-being. There are debates about the underlying causes of the association between residential demography and indicators of health and mortality (e.g., Hearst et al., 2008; Williams and Collins, 2001). It is plausible, for example, that this association can be explained by economic factors, with more segregated neighborhoods tending to have higher levels of poverty, poorer access to resources (e.g., health care, employment, and education), and greater exposure to negative environments (e.g., poor housing quality, exposure to pollutants and smog). Social problems such as violent crime and drug use also tend to concentrate more in segregated than in diverse communities. Exploring the additive and interactive effects of these kinds of variables on health and health-related behaviors is an ongoing project. Acevedo-Garcia et al. (2003) offer a systematic review of the field and some useful suggestions for directions in which it might develop.

The second example concerns the effects of racial diversity and segregation on residents' achievement. It is well-documented, for example, that highly segregated residential environments are also environments in which economic and educational achievement is retarded (e.g., Massey and Denton, 1993), even when controlling for the more direct impact of school segregation. Card and Rothstein (2006) explored the effects of residential segregation on the racial gap in the SAT scores of black and white students and reported: (1) that this gap is higher in more segregated cities, (2) that neighborhood segregation has a more consistently negative effect on the gap than school segregation, and (3) having controlled for variance contributed by factors such as family background, moving from a 'fully segregated' to a 'fully integrated' city narrows the achievement gap by around 25%.

Similarly, in a book on the consequences of being trapped in poor, racially segregated environments, Sharkey (2009) has recently presented an important summary of research on what happens if residents either escape the ghetto via residential mobility or if their neighborhoods become more diverse and prosperous through economic investment. The results of this research are complex. Nevertheless, they offset simple, pessimistic accounts of the role of neighborhood level factors in shaping achievement. **Figure 4** depicts, for instance, the result six studies of the effects of moving out of impoverished racial ghettos on children's reading and language skills, expressed as standard deviations of the effect size of improvement (or decline) in test scores. As is apparent, the majority of studies showed some improvement in children's skills as a result of mobility and in only one case was there evidence of decline (See Sharkey (2009) for a far more nuanced interpretation of these data and also for an important discussion the role of

Figure 4 Effects of leaving high-poverty neighborhoods on children's reading/language skills. Note: the *x*-axis lists the name of the study; the *y*-axis shows the estimated effect of neighborhood change on test scores, expressed as an effect size.

neighborhood change as a mechanism for achieving economic and educational mobility.). In at least some circumstances, it seems, leaving the 'dark ghetto' is beneficial not only for residents' wealth and health, but also for their cognitive skills and attainment.

Conclusions: Controversies, Debates, and Future Directions

> At best, their writings reflect their identification with the pervasive racism of the society within which they were socialized and with which they are now identified. They share the values and perspectives of their political and educational peers. Many of them are 'practical' and 'realistic' as they accept and seek to justify the racial rationalizations of the society of which they are a part.

Clark's (1979) indictment of social scientific resistance to desegregation captures a defining feature of the field. Because desegregation has such significance for issues of social justice and intergroup harmony, as we hope to have shown in this brief article, research inevitably blurs the line between scholarship and advocacy. The field is characterized by heated political debates, polarized positions, and ongoing controversies. Desegregation is itself an essentially contested concept, with little agreement about what forms it should take in particular settings. In this concluding section, we outline two current areas of controversy and debate, which also highlight some directions in which research is currently developing.

Understanding the Persistence and 'Adaptability' of Segregation

As should be apparent already, research on the role of desegregation in promoting social equality and harmony is haunted by an inconvenient truth. In many historically divided societies, despite state interventions and well-meaning policies to promote integration, segregation has never truly disappeared. It is alive and well. The well-documented retreat from Brown and the continuing – and in some cases increasing (Reardon et al., 2012) – high levels of racial segregation of American schools provides a symbolic case in point that is, of course, difficult to disentangle from the tortoise-slow process of residential desegregation in many American cities (Pettigrew, 2004).

The persistence of segregation in the United States is by no means unique. For example, the first and second authors of this article have lived and worked for most of their lives in two historically divided societies, namely South Africa and Northern Ireland. In our own lifetimes, both societies have undergone remarkable transitions to democratic government that brought about the end of armed conflict, the creation of new constitutions, and sweeping changes to promote social equality. Those transitions were also expected by many observers, including ourselves, to bring about wide-scale processes of desegregation, and in some contexts they did. However, even the most optimistic analyst would concede that South Africa and Northern Ireland, like the United States, remain deeply segregated societies. Moreover, research in both societies reveals how segregation is able to adapt and metamorphisize during periods of social change, reemerging in new forms. As the Group Areas Act and similar apartheid legislation was swept aside in South Africa, for instance, whites increasingly retreated into fortified enclaves and security villages and to the safety of shopping malls and other semi-'privatized' spaces of leisure and consumption (see Hook and Vrdoljak, 2002 for a dramatic example). Their current levels of residential segregation from other groups remain high and continue to correlate strongly with their wealth and privilege. Similarly, as Northern Ireland made the transition from sectarian violence to a postconflict society, the peace walls and interface barriers that historically separated protestant and catholic communities actually proliferated in number and size. Nearly a decade and a half after the signing of the Good Friday Agreement, Belfast, the country's capital city, remains organized along starkly sectarian lines (e.g., see Jarman, 2012).

For those interested more specifically in the role of desegregation in promoting new forms of intergroup contact, the adaptability of segregation is further illustrated by recent research on its so-called 'microecological' expressions within everyday 'activity spaces' (see **Figure 5**). This work is beginning to show how the spatial organization of relations in supposedly desegregated contexts such as university lecture theaters and dining halls, school classrooms and playgrounds, public seating areas, public transport, and spaces of leisure may reproduce racial segregation at a microinteractional scale (e.g., Dixon and Durrheim, 2003; Tredoux and Dixon, 2009; Orr et al., 2012; Swyngedouw, 2013). Drawing on methodological advances in studying human mobility in cities, it is also beginning to show how segregation is reproduced via the everyday timing and spacing of ordinary activities (e.g., Palmer et al., 2014; Wong and Shaw, 2011; Wang et al., 2012); that is, how recurring patterns of division and integration emerge as citizens travel each day through the city, selecting some pathways but avoiding others, and timing their itineraries so that they encounter the 'right' kinds of people, while distancing themselves from the 'wrong' kind.

Such research is deeply troubling. It seems that even in contexts where desegregation is actively promoted and where legal segregation has been abolished, intergroup contact may occur infrequently. For this reason, in their state-of-the-art review of contact research, Pettigrew and Tropp (2011) have called for a better understanding of the 'leading a horse to water' problem. As illustrated by our earlier discussion, we now know a lot about the nature and consequences of contact between groups and about the conditions under which it facilitates prejudice reduction. We know far less about why, even in the face of institutional pressures to integrate, individuals continue to act in ways that reproduce segregation.

Writing as social psychologists, we suspect that emerging forms of segregation cannot be explained entirely by distal economic, historical, legal, or institutional factors, however important those factors remain. As research on its microecological expressions in everyday activity spaces reveals, segregation is also, at least in part, a reflection of individuals' behavioral choices in their day-to-day lives. Understanding what underlies those choices is nowadays a matter of

Figure 5 Mapping the microecology of segregation on a South African beach (see Durrheim, K., Dixon, J., 2005. Racial Encounter: The Social Psychology of Contact and Desegregation. Psychology Press, London for more detailed discussion). Note: each black circle = one black person; each white circle = one white person; each black triangle = one Indian person.

considerable controversy. There is a fairly broad consensus, for example, that residential segregation in the United States is substantively driven by choices made by white home-owners and renters about where and with whom they want to live (e.g., see Charles, 2003; Dawkins, 2004). However, there is intense debate about the nature of the motives and beliefs that underpin those choices. For some, they express a kind of 'benign ethnocentricism' in which – here researchers often use Schelling's classic simulations as a touchstone – a little bit of in-group favoritism leads to an awful lot more segregation than anyone could anticipate (e.g., Clark et al., 2004). For others, this is a rather 'innocent' interpretation that misses the impetus behind preference driven segregation (e.g., Krysan et al., 2009). As Zubrinsky and Bobo (1996) observe: "… it is not merely empirically untenable to assert that simple economics or a morally innocent mutual ethnocentrism are major components of the process of racial residential segregation: these are egregiously mistaken analyses given our results and those of recent studies… Race matters. And it matters not merely because members of any group prefer 'their own kind,' but because everyone is aware of and must adapt to the historically developed, structurally rooted, and psychologically unavoidable American racial order or hierarchy" (p. 372).

Let Them Eat Harmony? Some Ironic Consequences of Intergroup Contact and Desegregation

As we have seen, a central benefit of desegregation is that it enables interaction between formerly divided groups and that this process, in turn, leads to more harmonious intergroup attitudes and relationships. Although research in some institutional contexts (e.g., schools) has produced mixed findings, there is a growing consensus that intergroup contact generally reduces prejudice, particularly when it occurs under Allport's (1954) optimal conditions. Recent debates, however, have raised questions about the model of social change that underpins the contact hypothesis (and similar prejudice reduction interventions), which is based on the idea that discrimination and inequality can be reduced if we can get the historically advantaged to have more positive thoughts and feelings about others (Dixon, 2012a,b; Reicher, 2007; Wright and Lubensky, 2009; Reynolds et al., 2012).

The limits of this perspective are evidenced in particular by the research on the effects of intergroup contact on the political attitudes of the disadvantaged, a relatively neglected area of research. Dixon and colleagues found, for example, that positive intergroup contact improved blacks' emotional responses toward whites in postapartheid South Africa, in line with the predictions of the contact hypothesis, but also shifted their political attitudes in a conservative direction (Dixon et al., 2007, 2010). That is, contact reduced their perceptions of own-group relative deprivation and discrimination and decreased support for policies designed to combat racial inequality in the postapartheid era (e.g., affirmative action). Researchers working in other countries with other kinds of intergroup relations have reported similar findings (e.g., see Glasford and Calcagno, 2011; Saguy et al., 2009; Sengupta and Sibley, 2013). The overall message of this emerging work has been relatively consistent across research programs. Intergroup contact encourages us to like one another more and reduces negative intergroup stereotypes. However, these benefits come at the cost of decreasing the political awareness

of the historically disadvantaged, fostering acceptance of systems justifying beliefs, and producing a 'sedative effect' (Cakal et al., 2011) on collective action to promote social change.

In the light of this kind of critique, researchers have been exploring several possible routes forward. Along these lines, Dixon et al. (2013) have recently outlined the so-called incommensurablist, compatibilist, and contextualist responses to arguments about the limits of a prejudice reduction model of social change. The overarching point to be taken from this debate is not, in their view, that the creation of intergroup harmony through contact and desegregation is somehow inherently problematic. To the contrary, there are many contexts in which getting people to like one another more is a valuable end in itself. Rather, this debate raises important questions about the conditions under which different forms of contact may produce different kinds of social, psychological, and political change. It thus invites us to reflect anew on about what kind of model of social change could or should be informing the process of desegregation and what we wish to accomplish by removing barriers to interaction between groups.

Abstract

The article reviews the structure of desert claims – the deserving, the deserved, and the desert bases – as well as their pre-institutional and institutional forms. It reviews the distinctions among desert, merit, and entitlement, considers their moral force, and engages with rejections of desert claims.

In everyday discourse, the language of desert is prominent and pervasive. It is common to speak of certain conduct (or persons) as deserving of praise or blame, reward or punishment, and of goods or ills that are visited upon people as deserved or undeserved. The subjects of desert claims may vary: most commonly they are persons or person-related entities (such as paintings that deserve prizes or cities that deserve their reputations), but insofar as inanimate or natural objects (such as rock formations) are evaluable in some way, there may be no barrier to speaking of them also as having deserts of certain kinds. The objects of desert claims are almost always seen as goods or ills. Inter alia a person may deserve success or failure, a good or bad reputation, good or bad luck, a greater or lesser portion of some social resource, compensation, or fairness.

Desert and Merit

The terms 'desert' and 'merit' are often used interchangeably. Some writers, however, have insisted on their conceptual distinction. If, for example, the ancient tie between diligence and desert (*deservire*: to serve zealously) is focused upon, the language of merit may be used to capture those outcomes warranted by other forms of value. Milne, for example, argues that:

> a natural beauty spot is *worthy of*, *merits*, or *rates* inclusion in a published guide to places of natural beauty, but it does not make sense to say that the inclusion in the guide is something *deserved* in the way of reward. The classification of human beauty (intelligence, or skill) is a parallel case: the naturally beautiful person merits a certain rating, but he or she does not deserve it any more than Niagara Falls is *rewarded* by its rating as a tourist spectacle. Only insofar as effort is expended in producing the achievement or contribution, or in acquiring a skill, is there the basis of a desert claim: a person cannot be deserving of praise or reward without trying. (Milne, 1986: p. 240)

The point is expressed generally by Pojman. Merit (or demerit), he claims, is the more inclusive term, referring to "any feature or quality that is the basis for distributing positive [or negative] attribution," whereas desert is a species of merit, "typically or paradigmatically connected with action, since it rests on what we voluntarily do or produce" (Pojman, 1999: p. 86). He then distinguishes a secondary, negative, compensatory, or rectificatory use of desert, to accommodate cases in which – relatively faultlessly – a person suffers some evil and recompense is appropriately called for.

Although a distinction of sorts can thus be made, it is at best a soft one, since a great deal of current debate about desert (see Section The Rejection of Desert) has concerned the enhancement of arbitrarily possessed advantages through diligent effort or the exacerbation of disadvantages, including some relating to effort.

Preinstitutional and Institutional Deserts

In recent philosophical discussion, a distinction has frequently been drawn between preinstitutional and institutional deserts – between deserts that are said to be 'naturally' implicated by virtue of some characteristic/activity of their subject, and those that are attributable only within the framework of some institutionalized arrangement. A person is said – preinstitutionally – to deserve his good fortune, or – institutionally – to have deserved to win a particular prize. The former is often said to be prior to the latter: "desert is a 'natural' moral notion (that is, one which is not logically tied to institutions, practices, and rules)" (Feinberg, 1963: p. 70). In many of its attributions to humans, preinstitutional desert is tied to reactive attitudes – the sense we have of others' agency, of their sharing with us at the deepest human level (Strawson, 1962). And the rejection of preinstitutional desert is often associated with a deterministic naturalism (Scheffler, 1992), more recently manifested in neuroscientific inquiry (Greene and Cohen, 2004).

Those who contend that only institutional desert claims have a legitimate place in the understanding assert that talk of preinstitutional deserts assumes, contrary to fact, that the characteristics on the basis of which such claims are made are fairly distributed. But – such critics of preinstitutional desert argue – since people naturally and arbitrarily differ in the talents, capacities, and social environments that ground what preinstitutional desert claims would allocate to them, they cannot really be said to deserve such things, or their fruits (cf Rawls, 1971: pp. 104–106, 312–314).

Leaving these latter claims aside (see Section The Rejection of Desert), it may nevertheless turn out that the distinction between preinstitutional and institutional deserts is one of degree, more than one of kind. The good weather that – it might be said – *A* deserves for vacation makes sense in part because the social institution of providing vacations has a point (recreation) to which 'good weather' intelligibly relates. Where no social institution is in place, it is much more difficult to make a specific attribution of desert. Thus, given the institution

of punishment, it may be easier to argue that those who deserve it are wrongdoers, than to argue – *ab initio* – that what wrongdoers deserve is punishment. It may well be that doing good has positive deserts, and doing ill has negative deserts, but the specific character of those deserts, whether good or ill, may not be easily determinable independently of particular social institutions (that, admittedly, are themselves open to scrutiny). It is – in part – the difficulty in establishing what, preinstitutionally, people deserve that creates some of the moral space for contemporary debates about restorative justice. Certainly, wrongdoing deserves some form of negative response, but should that response take the form of punishment (narrowly understood as fines, imprisonment), or instead as confrontation, blame, reparation, apology, penitence, and so forth? Perhaps, given that deserts are not morally determinative, punishment itself has a preinstitutional form that need not always translate into its institutional form (Kleinig, 2011).

Desert and Entitlement

But even if the distinction between preinstitutional and institutional deserts is soft, it should not lead to a conflation of desert with entitlement. '*A* deserves *p*' is not equivalent to '*A* is entitled to *p*'. Deserts seem to function comparatively or incrementally – as more or less; entitlements tend to be absolute – either we are or we are not entitled to something. Because of his or her talent and the effort put into training, *A* may be the most deserving when it comes to winning the race. But if *A* pulls a muscle and has to withdraw, *A* is not entitled to the prize, or even to win. The purpose of a race may be to determine who is the fastest runner, and *A* may be the fastest runner and therefore deserve to win. But the rules of the race – which formalize the process of determining who is the fastest runner – will determine who is entitled to win. The entitlement rules may not always succeed in establishing the most deserving, and sometimes they may even serve to exclude the most deserving.

Moral and Nonmoral Deserts

Desert often functions as a moral notion, especially where fair distributions of social benefits and burdens are involved. But it need not do so. If a person deserves success, or deserves to win a prize, or deserves good weather, one need not be talking about moral desert. True, it may seem to align with a certain cosmic fairness, but this need not be moral in character. Even if deserts are paradigmatically moral, they shade off into the nonmoral. In asserting that the Niagara Falls is deservedly famous or that the Mona Lisa deserves its reputation or even that a person's efforts deserved a better result, one is not making a moral claim. Although desert is a normative notion, it is not necessarily a moral one.

The Structure of Desert Claims

It is generally agreed that desert claims have the implicit structure '*A* deserves *p* in virtue of *x*,' where *A* is the subject of the desert claim, *p* its object, and *x* its basis.

For the most part, the subjects of desert claims will be persons/personal conduct (individual or collective) or people-related artifacts/constructs (such as art objects, cities, and so forth), although common parlance sometimes extends the language of desert to environmental and other natural objects (the sequoia, for example, may be said to deserve preservation or its reputation).

The range of deserved objects is vast: to those mentioned earlier may be added inter alia jobs, wages, grades, respect, wins, and losses. Linking all such objects is their perception as goods or ills, as benefits or burdens, as valued or disvalued. Although there may be marginal cases in which one deserves to be treated neutrally rather than well or ill (Sverdlik, 1983: pp. 320–321), such cases are parasitic on a context in which the distribution of goods and ills is primary. Sometimes – as in the case of *A*'s good weather – what seems to be deserved is a state of affairs rather than some mode of treatment by others or some achievement of one's own.

There is an ambiguity in the negative claim '*A* does not deserve *p*'. It may mean, '*A* does not deserve *p* (but deserves *q* instead)' or '*A* does not deserve *p* (or *q*)'. In the former case, we may speak of *A* being nondeserving, in the latter case of *A* being undeserving.

Desert Bases

Desert claims are more than expressions of personal assessment. They are subject to public scrutiny and criticism. In particular, some proportionality between the desert basis and deserved outcome is presupposed, although the principle of proportionality stands in need of clearer articulation than it is generally given. So, although one might be inclined to say that a person who was injured in an automobile accident – because he or she foolishly refused to use a safety belt – deserved the injuries he or she suffered (although not to be killed), we would be reluctant to say of a person who failed to wear a safety belt that he or she deserved to get injured (although we might want to say that if the person gets injured he or she will deserve it).

Most writers on desert consider that desert bases must not lie in the future, but are instead constituted by some past behavior or characteristics already possessed by the deserving object (Kleinig, 1971: p. 73; Sher, 1987: pp. 150–193). Appeals to future consequences as bases for distributing benefits and burdens may sometimes be justified, but cannot be justified as deserts. Or, at least these consequences cannot be directly justified as deserts. As indirect desert bases, reference to future-oriented considerations may be more plausible. For example, it may be argued that, although a person may deserve *p* only in virtue of his past diligence, diligence may be valued as a virtue (in part) because of its consequential/productive significance.

A few writers, however, have argued that a desert base might lie directly in the future (New, 1992, 1995; Feldman, 1995: pp. 69–71). The examples used to sustain this thesis refer to some known future facts (say, death and suffering), on the basis of which its subjects are said to deserve some recognition now. It is not clear, however, that the examples show what they are intended to (Smilansky, 1994): either there is some past or present commitment that is the basis for the desert or the

language of desert is better replaced by that of distributional fairness.

Locating Desert Bases

It has been suggested above, and argued at length by others, that the nature of a desert base can be established only by going outside the concept of desert to external goals and values that inform the activity in relation to which *p* is said to be deserved (Cummisky, 1987; Lamont, 1994). That is, merely by looking at the concept of desert, we cannot tell – except in the most general terms – what a particular act or course of conduct deserves. Moreover, because the goals and values of the activities in question may differ, depending on the context, disagreements about deservedness can become intractable if this wider context is forgotten. Disagreements may also be chronically unresolvable if there is no clarity about the goals and values implicit in the activities or institutions in relation to which attributions of desert are made. In addition, of course, there may be a further debate about the appropriateness of the goals and values to the activities or institution in question, and that debate may also impact on a discussion of the appropriateness of a particular desert basis or on the deservingness of those who are the recipients of its benefits or burdens.

Consider, for example, the institution of paying wages or a salary for work. It may not be determinable – given only a person's expenditure of productive effort outside the context of an employment contract – what the person deserves: whether he or she should receive further opportunities, praise, good fortune, sustenance, free housing, or a wage/salary. But, given that we have in place the work-related institutions that we do, we might wish to argue that *A*'s work deserves – at a minimum, assuming that it is 'full time' – a living wage. If the work that *A* does is especially demanding and/or highly valued, we might want to say that it should be more highly rewarded. Even so – to simplify the illustration – we might view *A*'s work in at least two ways, and these may be considered separately or in combination. We may focus on the demandingness of the work, on its productivity, or on some combination of the two. If the former constitutes our focus, work that manifests great effort, even if minimally productive, will be seen as most deserving of remuneration (whatever we do about entitlements). If the latter is more significant for the particular institution, then productivity will provide the basis for remunerative desert, even if the achievement reflects native talent more than effort. Given that, for many social institutions, productivity and effort will tend to be correlated, we may decide to take both into account in determining what a person's remunerative deserts should be – although if we are not sure for how much each is to count, there may be interminable disputes about a person's deserts. In such cases, rules governing entitlements will enable the institutions to function.

Consider now the salaries earned by sports and pop stars. At one level, we might wish to claim that LeBron James and Lady Gaga deserve – in terms of the institutions within which they operate – the status they possess and the remuneration they receive. But it is also open to us to debate the social value our society has accorded to sporting and singing prowess and, if as a result we conclude that they are overvalued, we will also consider that they have received more than they deserved (albeit no less than that to which they were entitled).

Where, as in many human activities, effort and achievement tend to be highly valued as desert bases, it is sometimes asserted that the desert basis – whether it focuses on effort or achievement – must be something for which the deserving person is responsible or over which he or she must have a significant degree of control. So, for example, a person cannot plausibly be said to deserve punishment unless that in virtue of which punishment is said to be deserved is something for which the person can be held responsible.

It is, however, more likely that the issue of responsibility/control is to be settled by reference to the goals and values of the institution to which the desert is related rather than to some feature of desert itself. In the case of impositions such as punishment, the idea that they could be deserved without the triggering behavior being under the person's control would be deeply problematic – although some proponents of hard determinism have argued that punishment could still be justified on consequentialist grounds. On the other hand, there is no great problem involved in thinking that those who deserve to win beauty contests are trading on genetic endowments more than on personal effort. And if inanimate objects – such as the Grand Canyon – can be said to be deservedly famous, the question of responsibility does not even arise.

There are, moreover, institutional contexts in which attributions of desert seem to require that one not have had control over one's circumstances. Consider, for example, deserved compensation. Here the deserving party is not usually seen as being in any way responsible for the misfortune in virtue of which he or she is said to deserve the compensation. Suggesting that the person who caused the misfortune is responsible puts the responsibility in the wrong place, and it is not adequately put in the right place by suggesting that the person who is deserving had to be nonresponsible for putting himself or herself in the way of the misfortune. What is more, the compensation may be deserved even if the cause of the misfortune cannot be held responsible for bringing it about.

Thus, the issue of responsibility too is determined by reference to the activity or institution in relation to which the desert claim is made. Prizes may be distributed to reward achievement or some combination of achievement and effort; wages may be given to reward productivity or some combination of productivity, talent, social importance, and effort. Some of these are more closely associated with personal control than others.

Among those who have wished to assert a tight relationship between desert and responsibility – or at least between desert and certain kinds of objects, such as punishments – several subsidiary discussions have ensued.

1. One arises out of debates about personal identity. It has been argued (notably by Derek Parfit) that since our personal identity is constituted by our beliefs, a significant change in our beliefs will reconstitute our identity as other than it was, with implications for our deserts. Parfit considers the case of a person who, at 90 years, after

receiving the Nobel Peace Prize, confesses to injuring a police officer when he was 20 years. Given the changes he has undergone, he no longer deserves punishment for what he did: "just as someone's deserts correspond to the degree of complicity with some criminal, so his deserts now, for some past crime, correspond to the degree of psychological connectedness between himself now and himself when committing the crime" (Parfit, 1984: p. 326). Although Parfit's account of identity has come in for criticism, his discussion draws attention to an important assumption about the subject of desert claims (see Fields, 1987).

2. A problem has also surfaced in discussions of moral luck (Richards, 1986; or, more generally, Rosebury, 1995). If it is simply a matter of good or bad luck that certain consequences come about through *A*'s actions, should this bear on the matter of desert? Given that luck refers to something beyond one's control, it might seem as though it should not. Nevertheless, we often act as though it does. If *A* drives recklessly through the streets and – as a matter of bad luck – an innocent pedestrian happens to step out just as he or she passes, we will be inclined to see the injury or death as exacerbating the recklessness and making the person more deserving of whatever penalty might have been due to him or her. Richards disagrees. Deserts are, he thinks, reflective of character, and the character of an unlucky and lucky reckless driver is the same. He suggests that the difference is largely an epistemic one. We are to judge on the basis of what good reason we have to know about their deserts, and the person whose recklessness (or other failing) luckily results in no harm to others does not provide us with the epistemic basis for judging the person as severely as the person who – unluckily, but not surprisingly – injures the other person. "Luck … affects how we ought to treat him, not by changing what he deserves, but by changing the grounds on which we are obliged to judge" (Richards, 1986: pp. 200–201). "To a very large extent people are lucky only in our verdicts, not in what they deserve, and their luck must affect our verdicts because it affects our grounds for reaching them" (Richards, 1986: p. 206). Richards' position has not gone unchallenged: recklessness may not deserve what is normally attributed to the driver in the event of an accident (Adler, 1987: p. 247); moreover, we may be in an epistemically better position to judge the lucky driver's character because of his record of speeding tickets (Adler, 1987: p. 247). Furthermore, Richards fails to give appropriate regard to the way in which the actual harm exacerbates the situation.

Enumerating Desert Bases

In the *Nicomachean Ethics*, Aristotle asserts that "everyone agrees that in distributions the just share must be given on the basis of what one deserves, though not everyone would name the same criterion of deserving: democrats say it is free birth, oligarchies that it is wealth or noble birth, and aristocrats that it is excellence" (Aristotle, 1962: pp. 118–119). For a modern reader, this well illustrates the dependence of desert bases on the goals and values of the activities or institutions within which desert attributions are made. In a world that is now characterized more noticeably by institutions and values that give greater weight – on the one hand – to individual responsibility and effort and – on the other – to achievement and social contribution, the bases for desert tend to be similarly characterized. As part of the tension between individual and collective values, a tension is also seen between desert bases that focus on individual responsibility, diligence, effort, and those that are more outcome directed.

Effort/Diligence

Writers who emphasize the importance of effort as a distributive desert base usually limit it in various ways. The effort must be purposeful, in the sense of being directed to the ends of the activity that grounds the desert; it must display a certain level of competence, in the sense of bearing some reasonable relation to achieving the ends of the activity in question; and the activity itself must be normatively acceptable: "There is no question of rewarding murderers and rapists, no matter how much effort has been expended by them" (Milne, 1986: p. 240).

If two people put in the same amount of effort, but one succeeds, whereas the other does not, then it might be said that they are equally deserving in virtue of their efforts. If, however, I offer a reward (or, more correctly, a prize) to the person who succeeds, then only the person who succeeds deserves it. Here the desert has been institutionalized. Our language is blurred between prizes and rewards, reflecting an overlap that sometimes occurs in competitive situations – but it should not lead us to the conclusion that achievement is 'the' proper basis for award claims.

Achievement

Those who focus on the importance of achievement draw attention to the inadequacy of effort unless it embodies competence – that is, is likely to be productive. If brilliant *A* can effortlessly produce the goods that diligent *B* cannot, then *A*, and not *B*, is likely to deserve whatever rewards or benefits are associated with that achievement. However, if it is sheer luck that results in the outcome for *A*, it is not so clear that *A* is more deserving than *B*. Even in cases in which the focus is on achievement, there seems to be some gesture in the direction of purposive effort.

The Force of Desert Claims

What follows from the claim *A* deserves *p*? Several possibilities have been canvassed: (1) *B* ought to ensure that *A* gets *p*, (2) *A* ought – all things considered – to get *p*, (3) *A* has a right to *p*, (4) There is a reason for giving *p* to *A*, and (5) *A* would be presumptively justified in getting *p*.

Most of these options are implausible. (1) It would be a rare desert claim that imposed a duty on some particular party. If *A* deserves to be punished, it does not follow that the state or some particular person should inflict it; if *A* deserves to succeed, it is unlikely to fall to any particular person to ensure that he or she does so. (2) Even if desert claims imply that someone ought to get something, they do not provide an overriding reason for it. Suppose, for example, that *A* deserves

to be punished. There may, nevertheless, be countervailing – and overriding – reasons why *A* ought not to be punished: perhaps mercy ought to be shown, or the social consequences of punishment would be disastrous. The same would hold of good deserts: other considerations of social justice may take priority. (3) Is also much too strong. (4) Seems too weak – not just because there may be many other considerations (besides deserts) that constitute reasons for giving *p* to *A* – but because deserts seem to be quite strong reasons for giving *p* to *A*. (5) Represents most closely the force of a desert claim. Such claims are presumptively strong enough to justify *A*'s getting *p* even if, in a particular case, some countervailing consideration would defeat the presumption. In practice, the situation is more complicated. If, for example, *p* refers not to some preinstitutional generality, but legal punishment or a competitive prize, other conditions may be necessary if the *p* is to be justified. In such cases, a formalized desert-determining procedure (an entitling procedure) will take precedence over the nonformal assessment of deserts.

Desert and Justice

One way of understanding desert claims is claims about justice. John Hospers, for example, writes, "Justice is getting what one deserves. What could be simpler?" (Hospers, 1961: p. 433). Desert claims then would have the force of claims about justice. But many have thought that this way of connecting desert with justice is too simple (Feinberg, 1963: p. 90; Sher, 1987: p. 49; Slote, 1973: p. 333). Even so, these writers have retained some sort of conceptual link between desert and justice. After all, when people do not get what they deserve, our immediate response is to think that they have suffered unfairly or unjustly. It is one thing to say, however, that a person's deserts constitute a factor – albeit an important one – in deciding what justice requires, and another to say – with Hospers – that deserts are the sole determinant of justice. The justice of social institutions may affect what people deserve no less than their deserts may constitute a factor in determining how they are to be justly treated (Sher, 1987: pp. 206–210).

The Rejection of Desert

Although I have argued that desert bases need not refer to conduct for which people are held responsible; nevertheless, for some distributions desert bases need to be factors for which people can be held responsible. Punishment, I noted, can hardly be said to be deserved if the conduct for which it is said to be deserved is not conduct for which the person to be punished can be held responsible.

Rawls turned this point into a general thesis against the justice of desert-based distributions. He argued that the factors that are usually adduced as desert bases in the distribution of social resources are not really things for which people can be held responsible. Those who have greater abilities and hence greater achievements have them because of their 'greater natural endowments,' not because of something for which they can be held responsible. Even a person's "character depends in large part upon fortunate family and social circumstances for which he can claim no credit" (Rawls, 1971: p. 104). It is "one of the fixed points of our considered judgments that no-one deserves his place in the distribution of native endowments, any more than one deserves one's initial starting place in society" (Rawls, 1971: pp. 103–104). Not even effort will get around this. "Even the willingness to make an effort, to try, and so to be deserving in the ordinary sense is itself dependent upon happy family and social circumstances" (Rawls, 1971: p. 74).

Although many have interpreted Rawls as taking a deterministic position on effort and achievement – seeing all effort and achievement as the inevitable outcome of native endowment and social opportunity – Rawls's rejection of desert is actually less categorical. He does not argue that we are only what we are born and bred to be, but that the task of separating out the various factors that have contributed both to our effort and to our achievement – those for which we are responsible from those that represent our endowment and opportunities – and thus enable an assessment of desert, is 'impracticable' (Rawls, 1971: p. 312). Judgments about deserts should, therefore, be excluded from assessments of social justice. Curiously, Rawls does not draw out the same implications for his briefer discussion of retributive justice.

If we allow that deserts need not depend on things for which we can be held responsible, it might not seem so problematic to maintain both that the traditional desert bases can be used as one possible ground for distribution, and also that these are not things for which we can be held – in any strong sense – responsible. Nozick has argued that "it needn't be that the foundations underlying desert are themselves deserved, all the way down" (Nozick, 1974: p. 225). If I win a race in part because of my natural talent, I may plausibly claim to deserve the prize. My personal desert does not presuppose that my talent was also deserved.

Nozick's critique goes further. Rawls infers from the arbitrariness of natural talent that such talents should be seen as common assets. Nozick does not see how the arbitrariness and undeserved nature of their natural distribution serves to disqualify those who have them from benefiting from them. Since the holdings that come into the world are already held, is it not plausible to assume that those who fortuitously have the holdings are 'preinstitutionally entitled' to the benefits that flow from them? Plausible, but not self-evident. We may consider it appropriate to grant the naturally talented and socially advantaged the benefits that flow from their fortuitous position, just as we may consider inherited wealth an entitlement of those who benefit from it. But it is hardly more obvious in the former case than in the latter that this is a matter of desert. If it appears so, this is because it is usually the case that the naturally talented and socially advantaged have to make something of their own of the endowments and opportunities they have received.

In its own way, the contemporary debate about personal desert reflects a much larger social debate about the extent to which our individuality – and that which might be said to flow from that by way of our share of social goods and ills – is viewed simply through the lens of our efforts and achievements, and the extent to which those efforts and achievements are considered as elaborations of a social

environment that has fostered and sustained them. Because the answer is unlikely to lie at either extreme, the defense of desert will inevitably be qualified.

This article opens with a short discussion about organizational design and form arguing that it is not just about structure although that is a commonly held belief. Then follows a history of the three main theories (rational, natural, and open systems) that impact organizational design and suggest that this systems theory of organizations is giving way to one based in complexity sciences. Because these theories are both competitive and complementary, the following section argues for taking a multiple perspectives approach to organizational design and form and shows why this is useful by drawing links to other subjects that influence it. Finally, three major directions for developing new knowledge on the topic are presented.

About Organizational Design and Form

Organizational design and form is still often taken to be the 'structure' of an organization. To improve organizational performance, there is a tendency to 'reorganize' or 'restructure' the reporting relationships between internal functional departments as shown on an organization chart and the associated coordination and linking mechanisms that facilitate the flow of information/resources between and among the business units. This view that 'structure' was synonymous with 'design' and that a 'right' structure could be developed for an organization may be traced to organization theories prevalent during the mid-/late 1970s, and based in mechanistic systems theory. At this point, Bob Duncan was able to say confidently: "Organization design is a central problem for managers. What is the 'best' structure for an organization? … This article discusses the purposes of organization structure and presents a decision tree analysis approach to help managers pick the right organization structure" (Duncan, 1979: p. 59). He went on to state that: "In discussing organization design … Organization theorists describe structure as more or less formalized, centralized, specialized, or hierarchical" (p. 61).

But consider a more recent definition of 'organization' as "a social arrangement for achieving controlled performance in pursuit of collective goals" (Huczynski and Buchanan, 2013). To make that definition come alive in the day-to-day work of an organization means thinking about design and form as much more than the 'structure' described by Duncan. Design and form emerges from making conscious decisions about explicit things like key partners, key activities, key resources, value propositions, customer relationships/segments, channels, cost structure, and revenue streams.

Yet design and form is not only about these explicit, easily described, aspects. It is also about recognizing (if possible) the power and impact of the tacit aspects of an organization – the ones that frequently defy conscious decisions made in relation to them. Such aspects include the cultural norms, social behaviors, management styles, organizational politics, language and tone, intuition, insights, decision-making processes, conflicts, emotions, and all the dimensions of work that are hard to pin down (Nonaka and Takeuchi, 1995).

These tacit aspects are integral to organizational design and form as becomes clearer when the idea that organizations are born from conversations is presented. Conversations are undirected exchanges with participants drawing meaning from each other's speech, building on what has gone before, and in the course of the discussion deriving a collective understanding of possibilities. Hewlett–Packard (HP), for example, established in 1939 developed from conversations between original founders David Packard and William Hewlett as they developed an audio oscillator in a garage. Their first customer was Walt Disney Studios who ordered eight of these. Over decades the company has developed into a global provider of software, hardware, and associated services. An organization does not spontaneously spring into being. It grows from interactions between people who share thinking and interests and focus toward a common goal (e.g., fulfilling a first order). Founder stories are rich sources of information on how organizations emanate from conversations.

These explicit and tacit organizational 'ingredients' are not working in an enclosed 'container.' They are influenced and mixed by constantly moving external conditions: shifting politics, rising environmental concerns, changing patterns of society/demography, increasing types of information and communication technologies, and demanding new legal/compliance requirements to name just a few. These too influence an organization's design and form (and are influenced by it).

Thus to see organizational design and form only in terms of structure is to get a very partial view of an exceptionally rich

arena. Certainly, the one element to be considered in 'designing' is an organization, but perhaps it is no longer the one to be considered dominant or even hugely important. As research on 320 companies on the relationship between structure, functioning, and effectiveness reported: "no direct relationship between structure and effectiveness was found. When functioning is conceptualized as a mediating factor no direct causality between structure and effectiveness is implied. … To improve effectiveness re-organizing is probably not the first option to consider" (Andersen and Jonsson, 2006: p. 257).

Theories of Organizational Design and Form

Over the years, organizational researchers and commentators have theorized from a variety of perspectives on the most efficient and effective way of organizing people to work collectively to achieve a specific purpose or outcome. Theorists broadly fall into one of the two schools: the systems (rational) school that focuses attention on the explicit elements of organization and the human relations (natural) school that focuses attention on the tacit elements of organization (Gouldner, 1959). The distinction is somewhat artificial as each school recognizes its interdependence with the other, but the 'angle of approach' as it were is what differentiates one from the other. Additionally, each of those schools is itself fragmented, offering often competing, contested, and conflicted perspectives and theories on organizations and each is continuing to advance its theories.

The rational systems school traces its roots to the early 1900s with the publication of Frederick Winslow Taylor's Principles of Scientific Management. At this point, organizations were observed as more or less closed systems operating independently of their context. They "exhibited a high degree of formalization. The co-operation among participants is 'conscious' and 'deliberate'; the structure of relations is made explicit and can be 'deliberately constructed and reconstructed.' … A structure is *formalized* to the extent that the rules governing behavior are precisely and explicitly formulated and to the extent that roles and role relations are prescribed independently of the personal attributes and relations of individuals occupying positions in the structure" (Scott, 2003). In this conception of organizations, their form and design could be consciously determined, sculpted, and shaped to achieve a specific goal or goals.

The natural (human relations) school has origins in the work of Chester Barnard and Elton Mayo in the late 1930s. Mayo, in contrast to the scientific view of management promulgated by Taylor, was of the view that "So long as commerce specializes in business methods which take no account of human nature and social motives, so long may we expect strikes and sabotage to be the ordinary accompaniment of industry" (Harvard Business School and Baker Library Historical Collections, n.d.). The focus of this school of thought was on the individuals working in the organization; their social relationships and their motivations and rewards for contributing their effort to meet organizational goals. "It is their energy, their ideas, their conformity and non-conformity that constitutes and shapes the structure of the organization and carries on its functions" (Scott, 2003).

By the mid-1960s, in signs of some partial unity between the two schools, theorists in both camps were examining the notion that design starts with the business strategy, and were describing organizations as open systems responsive to their environment. In *Differentiation and Integration in Complex Organizations* (Lawrence and Lorsch, 1967: p. 1), for example, the authors explain: "This is a comparative study of six organizations operating in the same industrial environment. The subsystems (sales, research, and production) in each organization were differentiated from each other in terms of subsystem formal structures, the member's goal orientation, member's time orientations, and member's interpersonal orientations."

From this and similar research (e.g.,.Thompson, 1967) contingency theory was developed. Briefly put, this suggests that organizations vary in design and form contingent on their operating environment and the types of products and services they are offering. Theorists agreed that there is no one right design and form for organizations or even an organization. What is 'right' depends on a number of variables and the way these interact to shape and be shaped by their operating environment.

Even so, until the early 2000s, there was a prevailing view that in order to function effectively and achieve performance success, organizations needed 'fit,' 'congruence,' 'alignment,' and/or 'equilibrium' between various organizational components and subsystems. Nadler and Tushman, talking about their congruence model, for example, commented that "strategy drives organizational architecture, a term that describes the variety of ways in which the enterprise structures, coordinates and manages the work of its people in pursuit of strategic objectives. … The more closely each component of the organization is aligned with the others – and with the strategy – the more effective the organizational performance" (Nadler and Tushman, 1999: p. 46).

Organizational systems models (showing the components for 'alignment') were developed in line with this thinking. Ones in common use from the early 1970s (and still used 40 years later) include the Star model (Galbraith, 1973), 7-S model (Pascale and Athos, 1981), Congruence model (Nadler et al., 1992), Burke Litwin model (Burke and Litwin, 1992), Weisbord's six box model (Weisbord, 1976), and Leavitt's Diamond model (Leavitt, 1965).

These models are useful as shorthand for thinking about an organization's design and form from more than one angle, but limited in that they cannot convey the interactions, emotions, and experiences of organizational functioning from either a rational or a natural or open systems perspective. Anyone who has worked in or with an organization will be clear that thinking dogmatically about it solely in terms of 'components' would not work to introduce, maintain, or develop a design and form that resulted in 'a social arrangement for achieving controlled performance in pursuit of collective goals.'

Additionally, getting to 'alignment,' which all the models aim toward, implies reaching a point of stability which could never happen: all organizations are in a constant state of flux (people leave or join, competitors emerge, other external factors come into play, and so on). So even without conscious design work, an organization's design and form is constantly changing in unpredictable ways: design works with paradox – design and

form is planned and emergent, explicit and tacit, systematic and conversational, enabling and constraining, differentiated and integrated (Rodgers, 2010).

Recognizing the inherent paradoxes in organizational design and form fosters a more spontaneous, potentially self-organizing view of organizations where order emerges from disorder. This finds voice in management researchers who are, in a departure from systems thinking, looking for insights from complexity sciences 'as a source domain for analogies' (Stacey et al., 2000). Stacey, among others, has come to view organizations as complex patterns of interactions that involve conversations, power dynamics, social cuing, cultural norms, and so on between individuals as they seek to explain and make sense of something, agree a course of action, or simply work together. Even with formal controlling structures like performance management systems, grade levels of staff, and rewards and penalties, the outcome of the informal interactions is not predictable or certain. This uncertainty results in ongoing interactions to create an organizational direction and future (Stacey, 2012).

Taking Multiple Perspectives

Although some theorists and academics stoutly defend their perspectives, others, for example Hatch and Cunliffe (2006), observe that it makes sense to commit to not a single perspective on organizational theory but a multiple perspective. And another academic who has done just that – committed to multiple perspectives from which to consider design and form – is Gareth Morgan. In his book *Images of Organization* he presents eight images (metaphors) of organization: machines (the systems perspective), organisms, cultures (the human relations perspective), brains, psychological prisons, instruments of domination, flux and transformation (complexity sciences), and political systems (Morgan, 2006).

Each one of these offers a multiplicity of ways in which to assess, interpret, and design an organization and each metaphor is associated with a large body of theory drawing from diverse disciplines that illustrate the many links that organizational design and form has to other subject areas: anthropology, architecture, strategy, communication, social and industrial psychology, culture, biosciences, economics, history, computer and information sciences, decision sciences, political science, and sociology to name but a few.

Additionally each metaphor offers a path to further theory construction and paves the way for the development of practitioner tools and intervention approaches – i.e., the 'how to' design methods. In presenting the eight metaphors, Morgan reinforces the notion that there is no 'right way' *to* design and form an organization and neither is there one right design or form *of* an organization. As he explains "Every metaphor is presented as a framework that generates both strength and limitations … Think 'culture' and you'll see all kinds of cultural dimensions. Think 'politics' and you'll find politics. Think in terms of system patterns and loops, and you'll find a whole range of them" (Morgan, 2011).

Taken as a set, it is easy to see in the eight images the competing and complementary theories of organizational design and form. There is practical value in recognizing that there is no unifying theory (or practice) related to it because the absence of an integrated theory 'shows the inherent incompleteness of any particular point of view.' As Morgan remarks holding only one perspective as "a way of seeing becomes a way of not seeing; and that any attempt to understand the complex nature of organizations (as with any other complex subject) always requires an open and pluralistic approach based on the interplay of multiple perspectives" (p. 466). It thus behooves leaders and organizational designers to consider a diversity of options, opinions, and possibilities as they strive to achieve 'a social arrangement for achieving controlled performance in pursuit of collective goals.'

New Directions for Knowledge

New directions for knowledge on organizational design and form are not easy to pinpoint. But there are three starting points to look for:

1. Bridging theory and practice in a way that develops actionable knowledge.
2. Looking at trends and fads that are 'out there' and potentially learning/developing knowledge from them.
3. Scanning, listening, and looking out for items of information that are not a trend or a fad but could have a big impact on 'connecting the dots,' or getting a completely new insight or perspective that developed new knowledge.

Bridging Theory and Practice in a Way that Develops Actionable Knowledge on Organizational Design and Form

Whether holding a single perspective of organizational design or form or a multiple one, in general academics tend to fight shy of discussing what will make the theories actionable in day-to-day organizational life: a gap exists between theory and practice attributed to a number of possible causes including academic 'fragmentation,' 'self-absorption,' and 'living in a self-indulgent state' (Starbuck, 2003). So although it is obvious that "there is a very large body of [theoretical] knowledge about organizations and organizing, examples of effective applications of this knowledge in designing real organization are few and far between" (Meyer, 2013: p. 16).

In the day-to-day (and as somewhat of a generalization), many organizational managers are distrustful of academic 'theory' and 'ivory tower thinking.' They just want something practical they can do to improve performance or achieve whatever it is that they are aiming for. And from the other side of the fence, academics are rather dismissive of fads and quick fixes that are not underpinned by rigorous and validated research.

Meyer, reporting on a 2013 organizational design community conference with both academic and practitioner participants, observed that "most established design efforts are rooted in a rational model of action … scholars should understand organizations, consultants should translate scholars' understandings and practitioners should take action based on understanding" but noted that several conference

participants "offered support for a model of action that accumulates knowledge through feedback from experience instead of through analysis and anticipation. … In this model action becomes the basis for understanding" (Meyer, 2013: p. 20). He presents a table of assumptions on the relationship between knowledge and action (Table 1).

The inherent danger of moving from one set of assumptions toward another is that the emerging assumptions become the new 'way it is,' leaving no room for competing and equally valid approaches. The risk of that happening could be minimized (and yield new knowledge) by testing each of the emerging assumptions individually and collectively in a variety of situations and by a variety of means: generating new metaphors, developing and testing scenarios, and working as a multidisciplinary team on real organizational design issues to get to a solution and simultaneously develop theory around it are some methods for doing this.

Model of action: Understand → Act → Evaluate	Model of action: Evaluate → Act → Understand
Designers must understand organizations before they attempt to change them.	Designers cannot understand organizations until and unless they try to change them.
Organizational design should be undertaken in an episodic or periodic fashion.	Organizational design should be an ongoing, continuous process.
Designing should be decomposed into specialized roles that are invoked sequentially. Scholars should understand, consultants should translate, and practitioners should implement.	Designing should unfold as an iterative sequence of experiments in which scholars, consultants, and practitioners collaborate in acting, evaluating, and designing.

Looking at Trends and Fads that Are 'Out There' and Potentially Learning/Developing Knowledge from Them

Trends and fads are not the same thing. A trend is month-by-month or year-by-year movement. Trends are often shown graphically as 'trend lines' drawn from quantifiable metrics collected over time. For example, the graphic below shows trend data for U.S. adults' Internet adoption between 1995 and 2013:

Source: Pew Internet & American Life Project Surveys, March 2000–September 2013. All surveys prior to March 2000 were conducted by the Pew Research Center for People & the Press.

A fad is a "transitory collective beliefs, disseminated by the discourse of management-knowledge entrepreneurs that a management technique is at the forefront of rational progress" (Williams, 2004) and because there is a gap between theory and practice, the field is left open for management fad adoption (a topic that is researched in its own right).

In the day-to-day, fads have a much heavier impact on organizational design and form than the impact of academic research and theory. As one academic notes, "the influential management fads-such as Japanese management, downsizing, reengineering, teamwork, Quality Circles, Six-Sigma quality management, the Learning Organization, outsourcing, knowledge management – have originated from managers and consultants" (Starbuck, 2003). In a challenge to the first emerging assumption in the table above, the adoption of the fads has been, in many cases, followed by academic research on their effectiveness (see, for example, Zairi et al., 1994) – so what is presented as an emerging assumption could also be an established assumption.

Managers in organizations are likely to be attracted to a fad if it is:

1. Simple to understand, easy to communicate, and associated with buzzwords and catchphrases.
2. Prescriptive in its approach – it tells manager what to do in things like seven steps, or five phases.
3. Encouraging of the successful outcomes by raising hopes even if there is little in the way of evaluative process attached to the sales pitch.
4. Universally relevant or one-size-fits-all as shown by exemplars who have already adopted the fad.
5. Easy to apply in practice or even partially apply by taking some elements of the method – this makes it easier to graft on to existing operations without whole scale change.
6. Able to speak directly to business issues of the day, e.g., to downsizing in a recession.
7. Interesting because of its novelty but not so radical as to disturb the underlying status quo.
8. Given legitimacy by consultants or and their successful devotees – an endorsement by a management celebrity and/or their followers goes a long way even without any evidence of true results (Miller and Hartwick, 2002).

Over time, some things that appear fads may become trends and then mainstream. In any event, adopting a fad or following a trend often has a learning value in its own right that makes it worth the investment assuming, of course, that there is conscious effort and reflective activity to generate the new knowledge perhaps through research and then theory generation as suggested above.

Scanning, Listening, and Looking Out for Items of Information

The third area for development of new knowledge is in what might be dismissed as random horizon scanning. Nevertheless activities such as following what futurists are saying (see the journal *Futures*, published by Elsevier which is concerned with the futures of international business), subscribing to a range of newsletters from the multiversity of disciplines mentioned above, and following blogs/tweets offering differing perspectives and world views are ways of contributing to the development of new knowledge. Two examples serve to illustrate: the first is an extract from an article on Bitcoin: "Peek into the future, and it's possible to envisage this sort of technology being used to cut intermediaries out of trades of many kinds – beginning with payment systems such as Visa and moving on to banks, real estate and more" (New Scientist, 2013) – this is exactly the type of snippet that an organizational designer working in the financial sector should seize on.

The second is the 'submit a hack' MIT: The Unlimited Human Potential Challenge inviting people to present case examples of the future of business. The challenge explains that "The Social Web and other digital technologies and platforms offer a robust set of alternatives to industrial-era forms of organizing. We now can imagine organizations

- Where coordination happens without centralization,
- Where power is the product of contribution rather than position,
- Where the wisdom of the many trumps the authority of the few,
- Where novel viewpoints get amplified rather than ignored or suppressed,
- Where communities form spontaneously around shared interests,
- Where opportunities to 'opt-in' blur the line between vocation and hobby, where titles and credentials count for less than value-added,
- Where performance is judged by your peers,
- Where influence comes from sharing information, not from hoarding it" (Management Innovation Exchange, 2013).

In fact, there are growing numbers of examples of organizations exhibiting these characteristics. Four that are gaining ground are 'sharing organizations,' 'crowd-sourced organizations,' 'virtual organizations,' and 'self-organizing networks.'

Sharing organizations are online services based on a principle that enable people to share the assets they own: cars, accommodation, bicycles, household appliances, and other items. Their role is to connect owners of underused assets with others willing to pay to use them. These types of collectivities are disrupting established companies in the sphere who are in turn starting to embrace the model themselves.

Crowd-sourced organizations are those that draw on society for input to their operation. Governments are increasingly looking to this as their budgets are reduced and their citizens are demanding more. Many are seeing opportunities to use digital technologies that give access to 'the crowd' to change the way they interact with citizens, save money, and provide services in new ways. As one commentator noted, "Many policymakers are beginning to look to society to help address social problems they know government cannot solve alone. The funding gap at the front-line is increasingly being filled by innovative financing mechanisms that blend private investment with public goals and a social return. Social media and open data are already forcing inward-looking bureaucracies to share decision-making and open up service delivery" (Cooper et al., 2013).

Virtual organizations comprise employees who are geographically distributed but who work effectively in groups or teams using available technologies. Call center and tech companies are increasingly known for this organizational form and others – including governments are moving toward a distributed workforce. The positives of a virtual organization include being able to access a very wide labor market, and offer employee benefits such as home working, or no requirement to relocate. The negatives are those associated with managing a distributed team and creating a sense of community and purpose necessary to achieve a common goal.

Self-organizing networks are the ones able to respond continuously to context changes without being hampered by restrictions of a rigid or well-established organizational infrastructure that might include policies, grading systems, and management controls. In these self-organizing networks, the resources and the individuals coalesce for a temporary period to achieve something that individually they could not do. Grassroots neighborhood organizations that form to protest against the closure of a manufacturing plant, or the siting of a power station, are typical of self-organization where leaders emerge 'in the moment.' Such organizations often disband when an outcome has been realized. Self-organizing like this is also seen within organizations – for

example, if there is a will to change a policy or develop a new direction. Some organizations, Google among them, actively encourage self-organizing interest groups to form with the intention that they will explore and develop ideas that could lead to innovative products and services. This self-organizing within an established enterprise is often the precursor or initiator of a new organizational form. All these four types of new organizational forms rely on information and communication technologies and have the potential to upend established organizational forms. It remains to be seen whether these and other new types of organizations arising in emerging circumstances with new technologies will displace the established organizations, whose design and form originated in different circumstances. Research appears to confirm that it is more often the case than not that they do. "With a few exceptions, the only instances in which mainstream firms have successfully established a timely position in a disruptive technology were those in which the firms' managers set up an autonomous organization charged with building a new and independent business around the disruptive technology" (Christensen, 2013 reprint edition).

Conclusion

This article opened with a quote that although said in 1973 holds true 40 years on. The field of organizational design and form is still polarized and struggling and that is what makes it fascinating. There is room for more research, deeper learning from practice, new theories, and much more.

Determinism: Social and Economic

Warren Schmaus, Illinois Institute of Technology, Chicago, IL, USA

Abstract

Social and economic determinism is the thesis that human beliefs and practices are to be explained by social and economic factors. However, sociologists rarely mean 'determine' in any mechanical, causal sense. Those such as Marx and Durkheim who have been considered determinists have typically argued that our beliefs and practices are adaptations to, rather than effects of, social and economic conditions. More recent versions of this thesis include the 'strong programme' in the sociology of scientific knowledge of David Bloor and his associates and the feminist standpoint epistemology of Sandra Harding and others.

Social and economic determinism is the thesis that human beliefs, practices, and actions are to be explained in terms of social and economic factors. Few social theorists have ever maintained this as a strictly causal, mechanistic thesis. However, critics will often interpret social and economic determinism in this way for rhetorical effect. When one looks more closely at major social theorists such as Karl Marx and Emile Durkheim who have been charged with economic or social determinism, they can be read as having offered functional rather than causal explanations of people's views. Karl Mannheim understood Marx this way. On this reading, people's religious or political beliefs are not caused by their social or economic positions, but rather have the effect of helping to maintain people in these positions. Explanations that appeal to social and economic interests, which the Strong Programme in the sociology of scientific knowledge have recently invoked to account for scientists' theoretical commitments, are functional explanations of this sort. Similarly, Michael Mann's accounts of the sources of social power are closer to interest or functional than causal explanations. Feminist standpoint epistemology borrows the Marxian or Mannheimian notion that a person's point of view may be explained in terms of their social location within a hierarchy of power relations, but allows for other contributing factors as well and is not fully deterministic.

Deterministic philosophies of one sort or another of course date back to the pre-Socratic philosophers, but the universal determinism defended by some philosophers and religious thinkers does not appeal to specifically social or economic causes. Nor would theories that explain social phenomena in terms of biological and physical causes be considered forms of social or economic determinism. Thus, Social Darwinists such as Herbert Spencer are not social or economic determinists. Social and economic determinism has its historical antecedents in sociologists like Auguste Comte and economists like David Ricardo, who held that social and economic phenomena are to be explained by specifically sociological and economic laws. Although Comte regarded sociological laws as deterministic, he did not give any empirical evidence to support this position. Indeed, he not could have. As David Hume argued, experience can show us only that one thing has always followed another; it can never show us that these things *must* follow in this way. Like Spencer and other nineteenth-century social theorists, Comte appears to have unwittingly introduced a metaphysical assumption into his social science.

Causality and Determinism

This idea that human beliefs, practices, and actions are determined is often confused with the claim that these results are inevitable and predictable. However, phenomena may not be predictable if the conditions on which they depend are either unknown or, even when they are known, are so complex as to make it humanly impossible to deduce their consequences. Also, one may believe in inevitability for mystical or spiritual reasons. Nevertheless, for whatever reason one holds the thesis that the course of human events is inevitable, it is a metaphysical claim that cannot be empirically tested.

Causal deterministic laws have the form "under conditions C, effect E will result," in which C is said to be a sufficient condition for E. That is, in a deterministic law, the relationship between cause and effect is not merely probabilistic or statistical. It is invariable and unconditional. However, even those such as Ludwig Gumplowicz who maintain that social phenomena are governed by deterministic laws rarely, if ever, provide examples of such laws. Their putative causal claims and the arguments put forth in defense of them typically fall short of providing a set of conditions sufficient for determining the beliefs, practices, or actions to be explained. Frequently, at best merely necessary conditions are given. Sometimes, even these conditions are necessary only under a certain set of circumstances.

Most often a purported causal relationship between certain social or economic conditions and the beliefs and practices to which they are supposed to give rise turns out to be a functional relationship instead. Functional accounts of beliefs and practices show them to be adaptations to, rather than results of, these and some additional social and economic conditions. A functional explanation differs from a causal explanation of some phenomenon by providing, instead of a sufficient condition for its occurrence, one of its effects that help to maintain that phenomenon in existence. Such an effect is only a necessary and not a sufficient or determining condition for that phenomenon. When providing a functional explanation, one must avoid the trap of simply pointing to what appear to

be the obvious beneficial consequences of that phenomenon and adduce actual evidence that these consequences actually helped to maintain that phenomenon in existence.

Marx and Economic Determinism

There are two different but related senses of determinism in Marxist thought. The first is historical determinism or materialism, according to which the course of history is to be explained through material or economic causes. The second is Marx's theory that what he calls the economic 'base' of a society, which consists in the modes and relations of economic production, somehow 'determines' a 'superstructure' of laws, politics, religion, and other ideological beliefs. Marx claimed to be offering not just another social philosophy or philosophy of history, but an actual science with deterministic laws that made it possible to predict the coming proletarian revolution in the most advanced capitalist economies.

Historical Materialism

'Historical materialism' is actually Friedrich Engels', not Marx's term. According to the materialist conception of history, there is an inevitable class struggle between the bourgeoisie and the proletariat. This belief has antecedents in earlier thinkers, most notably David Ricardo. For Ricardo, class conflict is the inevitable result of a population increase leading to the bringing of marginal lands under cultivation, which leads to wages dropping to a subsistence level. For Marx, on the other hand, class conflict was not a result of population growth but of changing modes of economic production. As new modes of production develop, they come into conflict with the social relations that existed under the previous economic system. The older social relations are encumbrances on these new modes of production. Eventually these older relations give way to new ones that are more in line with the new form of production. Each major change in the social relations of production, from slavery to feudalism, from feudalism to bourgeois capitalism, and from capitalism to socialism, is accompanied by class conflict.

Base and Superstructure

Marx appears to have thought that there are irreconcilable differences in thought between the bourgeoisie and the proletariat due to their different economic positions in society. According to Marx's famous 'Preface' to his *A Contribution to the Critique of Political Economy* (1859):

> In the social production of their existence, men inevitably enter into definite relations, which are independent of their will, namely relations of production appropriate to a given stage in the development of their material forces of production. The totality of these relations of production constitutes the economic structure of society, the real foundation, on which arises a legal and political superstructure and to which correspond definite forms of social consciousness. The mode of production of material life conditions the general process of social, political and intellectual life. It is not the consciousness of men that determines their existence, but their social existence that determines (*bestimmt*) their consciousness.

Although this passage has been read as suggesting that individuals are mere puppets pulled by economic and social strings, it is not at all clear that Marx meant 'determines' in any causal or mechanistic sense. The German word '*bestimmt*' means 'determine' in the sense of decide, define, set limits or boundaries to, or fix something, such as a price or time. Furthermore, the very building metaphor implied in the language of base and superstructure suggests that the form of economic life is at best a necessary condition and not a sufficient cause for that which rests upon it. On the mechanistic reading of 'determines', Marx would have been guilty of an inexcusable non sequitur from premises about necessary conditions to a conclusion about sufficient conditions. Finally, Marx objected to the practice of taking the causal powers of human beings and projecting them onto mere abstractions such as god, the state, or capital. In his *Theses on Feuerbach* (1845), he had criticized the materialists for doing this, and yet this is precisely what the mechanistic reading of the 'Preface' does.

If one reads 'determine' in the sense of deciding, Marx appears to have said that social and economic conditions choose or select rather than cause certain forms of thought. Marx would then have been using a form of explanation that Darwin, whom Marx much admired, had introduced in the *On the Origin of Species*, which was published the very same year Marx wrote this preface. Perhaps the clearest example of such a selectionist explanation in Marx is provided by his appeal to class interests in his account of the struggle between bourgeoisie and proletariat.

Class Interests and Functional Explanation

Under the capitalist mode of production, the bourgeoisie must constantly strive to maintain or increase their rate of profit to stay competitive. Since, to put it simply, the rate of profit is equal to the value of a product divided by the cost of its production, perhaps the best way to increase the rate of profit is to drive down the cost of production. However, part of these costs, such as raw materials and machinery, is fixed, according to Marx. Hence, the bourgeoisie must try to decrease the variable costs of labor, either by reducing wages or by replacing workers with machinery. However, as a greater and greater proportion of the costs of production go into the fixed costs of machinery and a decreasing proportion go into the variable costs of labor, it becomes increasingly difficult for the capitalist to find ways to cut costs. The capitalist is forced continuously to reinvest his profits in machinery in order to replace even more workers with machines and the remaining workers are reduced to a subsistence wage. According to Marx's law of capitalist accumulation in *Capital* (1867), the greater the wealth invested in fixed capital, the greater the misery of the proletariat. Class conflict is the inevitable result.

Economic class interests are not necessarily consciously thought by social actors, but rather are ascribed to these actors by the social scientist observing the situation. This is what Marx meant when he referred to them as 'objective' class interests. When he said that the class interests of the bourgeoisie and the proletariat conflict, what he meant is that a member of the bourgeoisie who acts in accordance with his objective class interests will thereby act in a way that directly conflicts with the

objective interests of the working class. Marx did not mean to say that being a member of the bourgeoisie actually causes one to think in a certain way, which is different than the way in which the proletariat thinks; indeed, it is not all that important or relevant what individuals may actually be thinking. For example, to say that it is in the class interest of the bourgeoisie to reinvest their profits in new machinery is to say that those capitalists who thus reinvest their profits will remain in the bourgeoisie while those who do not act in this way will not remain competitive and will eventually drop down into the proletariat. Thus, to say that the capitalist replaces workers with machines because it is in his interest to do so is to give a functional rather than a causal explanation.

Indeed, the alternative, causal determinist interpretation of Marx makes him out to be an inconsistent thinker. If our ideas were really determined by our class membership, what would be the point of writing manifestoes? How could he have hoped to change people's ideas through rhetoric and persuasion? One might object that his writings were addressed only to the working class. However, in the *Communist Manifesto* (1848) he described – with obvious reference to people such as himself and Engels – how a portion of the bourgeoisie, "who have raised themselves to the level of comprehending theoretically the historical movement as a whole", "cuts itself adrift" and joins with the proletariat. On the determinist reading of Marx, these claims appear embarrassingly ad hoc. A functionalist reading suggests merely that people like Marx have chosen a path in life that will not make them rich.

However, as G. A. Cohen (1978) points out, orthodox Marxists tend to resist the interpretation that Marx was offering functional explanations due to their tendency to associate such explanations with the functionalist tradition in the social sciences that has its roots in thinkers such as Durkheim and Bronislaw Malinowski. According to this tradition, a society or culture forms an organic unit, every element of which serves a function that helps to sustain the whole. Marxists regard functionalist social science as resistant to social change and thus as politically conservative. However, as Cohen argues, the use of functional explanations does not necessarily commit one to this brand of functionalism.

Economic and Social Determinism after Marx

Some would say that Engels, Karl Kautsky, Antonio Labriola, Lenin, Nikolai Bukharin, and others posthumously transformed Marx's theories into deterministic ones. Whether or not this is true of all these thinkers, Marx's theories were certainly understood deterministically in their role as the official ideology of the Soviet Union. They were incorporated into an entire deterministic worldview that included all of the natural as well as the social sciences. Thus Stalin suppressed theories in genetics and quantum mechanics that entailed that nature was not completely deterministic in its operations. How could the triumph of proletarian communism be determined if even the course of nature were not? Even mathematical theories of probability and statistics were prohibited in the Stalinist Soviet Union (Huxley, 1949).

Although Ludwig Gumplowicz was not a Marxist, he affirmed both social and economic determinism in *The Outlines of Sociology* (1885). For Gumplowicz, phenomena such as customs, languages, religions, and laws arise from the interaction of social groups. A person's thoughts, feelings, and tastes are all products of her social environment. Modes of living and thinking vary not only among what he considered the three major classes – the aristocracy, the bourgeoisie, and the peasantry – but even among the different trades and professions of the bourgeoisie. However, there is no rigorous use of evidence to support any of these claims or to demonstrate the existence of causal relationships and not merely a correlation between, say, class membership and a style of thought. Economic and social determinism had metaphysical implications for Gumplowicz: he argued that if there are universal laws governing social as well as physical and psychological phenomena, then monism is true and dualism is false.

Karl Mannheim's Sociology of Knowledge

Mannheim maintained a more subtle, sophisticated version of social and economic determinism than Gumplowicz. As he explained in the English version of *Ideology and Utopia* (1936), when he spoke of the 'existential determination of knowledge', he did not have a causal, mechanistic determinism in mind. The German term is *Seinsverbundenheit des Wissens*, which carries more the sense of connection, agreement, relationship, association, bond, or tie than one of causal determination between existence and knowledge. What Mannheim meant by the expression is that thought does not develop solely through some sort of inner logic, but is influenced by extratheoretical or existential factors that play more than a peripheral role in shaping our ideas.

Mannheim's essay "The Problem of a Sociology of Knowledge" (1952) presents perhaps the clearest exposition of his views. According to Mannheim, the sociology of knowledge, which investigates the existential determination of knowledge, has its origins in Marx's theory of ideology, which is characterized by an 'unmasking turn of mind'. To unmask an idea is not to refute it or deny its truth, but to ascertain its extratheoretical function, the social and economic interests that it serves, and thereby to undermine its practical effectiveness. For Mannheim, however, a person's ideas or beliefs do not depend on their social existence in any piecemeal fashion, but only as interdependent parts of an entire superstructure or worldview. The sociology of knowledge investigates the existential determination of this entire worldview, unmasking not single ideas but entire ideologies.

Mannheim also referred to these worldviews as styles of thought, standpoints, or world postulates. These are not static systems of ideas, but rather ways of thinking that are continuously developing and changing. At any given moment of history, there may be several different styles of thought. Marxism itself is simply one theoretical standpoint that corresponds to a particular phase of history. For Mannheim, the relationship between styles of thought and social factors is not a straightforward, causal one. The economic base and the superstructure are both mental realms for Mannheim, and both parts of the same evolutionary process. The sociology of knowledge investigates this evolutionary process and the functional relationships between intellectual standpoints and

social locations. Ideas change their meaning when their social function changes. One cannot identify once and for all time any given intellectual standpoint with any particular social stratum or class, as everything is constantly changing. Thus, for example, there is no such thing as a specifically bourgeois or proletarian style of thought.

According to Mannheim, Marxists recognize only one sort of correlation between social reality and intellectual phenomena: that is, that the latter are dictated by social interests. However, Mannheim thought that to attempt to explain anything other than political and economic theories in this way would only be to expand the notion of interest in such a way that it would lose all meaning. Nevertheless, economic theories are embedded in larger intellectual universes in such a way that someone with a direct interest in an economic theory may be indirectly committed to the artistic, philosophical, and other intellectual components that are part of the same universe as that economic theory.

Like Gumplowicz, Mannheim also recognized that social groups other than just the bourgeoisie and the proletariat – such as occupational groups, sects, and generations – play a role in the existential determination of ideas. Within the proletariat, for example, there are different groups each sharing a different worldview and belonging to a different political party, reflecting different social strata within the proletariat. The sociologist of knowledge investigates the functional dependence of each intellectual standpoint on the social group that stands behind it and traces the evolution of these standpoints.

Durkheim and Social Causes

Durkheim's works have been subjected to a variety of interpretations from materialistic and deterministic to idealistic. Deterministic readings are due in large part to the ambiguity of his sociological explanations: it is often not clear whether he was offering a causal explanation, functional explanation, or both. In *The Rules of Sociological Method* (1895), he insisted that social facts are to be explained by social causes and that these social causes are to be carefully distinguished from psychological and other sorts of causes as well as from social functions. However, he did not always follow these methodological prescriptions in his empirical sociological treatises.

The Causes of the Division of Labor

For instance, Durkheim's *The Division of Labor in Society* (1893) is often read as having made the deterministic claim that increasing labor specialization results from increasing population density. However, on a closer reading, he actually said that specialization results from an increase in what he called 'social density', or the degree to which individual human beings form social relations with one another. He also seems to have suggested that population density, along with the rise of cities and means of communication, is merely a symptom or sign of social density. However, because he made population and social density each the necessary and sufficient condition for the other, his interpreters have been confused about which is supposed to be the cause and which the effect. Hence, Durkheim was taken to have advanced the social determinist thesis that rising population density causes increased social density which in turn results in the division of labor in society.

Nevertheless, Durkheim explained that specialization is not caused by population or social density but is an adaptation to it, making explicit reference to Darwin's account of how a divergence of characteristics is naturally selected in the struggle for existence. Durkheim even mentioned alternative responses to population pressure, such as emigration. Specialization takes place only when the social bonds among individuals are so strong that emigration is out of the question.

Furthermore, nothing Durkheim said rules out the possibility that specialization could be a successful strategy for coping with other sorts of conditions besides social and population density. For example, hunter-gatherer tribes living under low-density conditions have been known to specialize in the natural products available in their territory, trading with other tribes for other things that they need. Hence, population density does not appear to be even a necessary condition for specialization. At best, it may be what J. L. Mackie (1974) has called an 'inus' condition, or an insufficient but necessary part of an unnecessary but sufficient condition, or, less technically, a condition that is only necessary under a certain set of circumstances.

The Social Causes of the Categories

Later in his career, Durkheim, along with Marcel Mauss and others, advanced a sociology of knowledge according to which our basic categories of thought, including space, time, causality, substance, and genus or class, are to be explained by social causes (Durkheim, 1912; Durkheim and Mauss, 1903). For example, they claimed that a culture's units for measuring time reflect the rhythm of its social life and its system of spatial directions is patterned on the distribution of clans at tribal campsites. The very practice of classifying things in nature by a nested hierarchy of genera and species reflects an elementary social structure consisting of clans subsumed under phratries.

However, Durkheim's sociology of knowledge is ambiguous between the causal claim that the categories result from social life and the functional claim that these concepts make human social life possible. He argued that every society needs for instance some method of indicating directions in space and measuring time, in order to organize social life and make communication possible. A society also requires some way of assigning causal responsibility, since law and morality depend on it. The evidence that the Durkheimians have marshaled in support of their theory actually shows that cultures have different ways of doing these things, which amount to different ways of representing what are more or less the same basic concepts, and that these cultural representations of the categories have social causes or at least social models. However, Durkheim was not entirely clear about whether all cultures shared the same basic concepts, because although he thought that these concepts were functionally necessary to society, he also claimed that it was possible for a culture to have a different system of categories, which would imply that concepts like space, time, and causality are not really necessary for social life after all.

Despite the ambiguity of Durkheim and Mauss's sociology of knowledge, it provided part of the inspiration, along with Edward Sapir and Benjamin Lee Whorf's linguistic determinism, for the sociological determinism of such British social anthropologists as Max Gluckman, Edmund Leach, and Mary Douglas. According to this view, because the concepts or categories through which people perceive the world are the product of their cultures, the very contents of their experiences will be socially and culturally determined. These social anthropologists, however, did not draw a clear distinction between mere classificatory concepts and the more fundamental categories of thought, such as the very idea of having a classification in the first place. Gluckman, for instance, included concepts such as shapes and colors among the categories that determine perceptual reality for us:

> From infancy, every individual is moulded by the culture of the society into which it is born. All human beings see, but we know, for example, that how they see shapes and colours is to some extent determined by this process of moulding. More than this, their ability to describe their perceptions depends on the categories contained in their respective languages.
> (Gluckman, 1949–1950: pp. 73–74)

This claim rests on dubious assumptions about the psychology of perception and is not supported by more recent anthropological research.

More Recent Determinism

The Strong Programme in the Sociology of Scientific Knowledge

In the 1970s, a group calling themselves the "Strong Programme in the Sociology of Scientific Knowledge" defended a determinist approach with roots in Durkheim and Marx. David Bloor (1976/1991), a principal spokesperson for the group, laid out four tenets for this program. They are (1) that explanations of belief and knowledge should be causal; (2) that sociology should be impartial with respect to the truth or falsity, or the rationality or irrationality, of the belief to be explained; (3) that explanation should be symmetrical, in the sense that the same kind of causes would explain both true and false beliefs; and (4) that the sociology of knowledge should be reflexive, in the sense that the same principles of explanation should apply to sociology itself. The Strong Programme regarded accounts of the beliefs and practices of scientists in terms of their social interests as satisfying the demand for causal explanation, although, as mentioned earlier, interest accounts are functional rather than causal explanations. Their concept of social interests included not only economic or class interests but political, religious, professional, and other interests as well. Thus, ironically, while criticizing Mannheim for failing to include the natural sciences within the explanatory scope of the sociology of knowledge, they also neglected his warning about expanding the notion of social interests to such an extent as to empty it of meaning.

Philosophers and other social scientists sharply criticized the Strong Programme. Philosophers insisted that scientists held the views that they did on the basis of reason and evidence. They furthermore argued that the tenets of impartiality and symmetry prevent the Strong Programme from arguing for their position on epistemic grounds: that is, these tenets prohibit them from saying that their beliefs are any more well founded than the alternatives. Among the social scientists who criticized them, some felt that in plumping for causal explanations, the Strong Programme was trying too hard to model the social on the natural sciences. Others criticized them for taking the existence of social structure and social classes as given and not recognizing that these are constantly changing social phenomena brought about through complex human interaction. Like Mannheim, these critics recognize that social structure and class exist in and through the beliefs and practices of the members of society and are to be explained in the same way as any other beliefs and practices. To explain a person's scientific beliefs in terms of social interests is thus in effect to privilege one sort of belief over another.

Feminist Standpoint Epistemology

More recently, a type of feminist social theory called 'standpoint epistemology' reflects the influence of Marx's social and economic determinism. Feminist standpoint epistemology is characterized by two related claims: the situated knowledge thesis and the privileged location thesis.

According to the situated knowledge thesis, what one knows or experiences reflects one's social, cultural, and historical location. As Alison Wylie puts it:

> What we experience and understand, the differential strengths and liabilities we develop as epistemic agents, are systematically shaped by our location in hierarchically structured systems of power relations, by the material conditions of our lives, by the relations of production and reproduction that shape our social interactions, and by the conceptual resources we rely on to interpret and represent these relations.
> (Wylie, 2007: p. 574)

The privileged location thesis says that some social locations are privileged in the sense of being more likely to produce true or reliable knowledge. According to Sandra Harding, the privileged location thesis has its roots in Hegel and Marx (1986: p. 26).

For Hegel, the slave enjoyed this privileged position relative to his or her master; for Marx, the proletariat occupies an epistemologically privileged location relative to the bourgeoisie. Feminist standpoint theory says that this privileged location belongs to women, especially feminist women.

Marx and Engels, recall, claimed that they were not putting forth a new social philosophy, but establishing a new science, based on observation, which revealed the direction in which history was determined. They also held that the proletariat was in a privileged position to observe the social conditions that determined this direction. Marx and Engels had assumed something akin to Francis Bacon's model of the methods of science, according to which scientific objectivity consisted in individual scientists freeing their minds of certain biases, or 'idols' as he called them, in order to observe and classify the

facts that could serve as the basis for general laws. For Marx and Engels, those who are in positions of power have more biases that interfere with gathering objective knowledge from experience than those who are socially and economically marginalized. This was because the bourgeoisie saw things only through the veil of an ideology that made possible their higher social and economic status. Members of the proletariat were encumbered by fewer such ideological biases than the bourgeoisie and thus enjoyed an epistemologically privileged location.

Similarly, for the feminist, men's minds may be clouded by the very ideology through which they maintain their power over women. However, the feminist standpoint theorist does not think that someone automatically enjoys an epistemologically privileged location simply in virtue of being a woman. Nor do all Marxists think that all members of the proletariat automatically enjoy an epistemologically privileged location. It is not always obvious to someone that he or she is being oppressed and it is possible for someone to succumb to the very ideology that helps to maintain them in an inferior social position. For the feminist standpoint theorist, an epistemologically privileged location is achieved as the result of an intellectual struggle. A woman may come to realize her oppression only through discussion with others and an analysis of her personal situation.

However, lacking a clear way to define social location, the privileged location thesis is difficult to test. Marx had assumed a simple linear hierarchy of power relationships. In contemporary society, one's social location is a function of gender, race, ethnicity, religion, sexual orientation, wealth, level of education, marital status, and other factors, not all of which vary together. Feminist standpoint theorists may reject the simple linear hierarchy of the Marxists, but the idea of a hierarchy of power relations persists in the notion of a center of power surrounded by a periphery of oppressed groups. But how does one measure and thus compare the distances from the center of these oppressed groups? And how can one test the claim that members of these groups see things more clearly? Even members of marginalized groups have their prejudices. Nevertheless, one could argue that marginalized social locations may be epistemologically privileged just to the extent they allow the prejudices of the dominant group to become more visible, regardless of the prejudices of the marginalized group. That is, the victims of oppression are in a better position to observe its effects, and perhaps to question the assumptions of the dominant ideology.

It is ironic that a social theorist like Marx would hold the Baconian notion that epistemological objectivity depends on the elimination of biases, since it assumes that the knowledge producer is the individual, rather than the community. From a social point of view, objectivity depends on critical interaction among of group of people, rather than each individual cleansing her mind of prejudice. The more that different people with various experiences and points of view contribute to this critical discussion, the more objective will be the result. Thus, regardless whether the privileged location thesis can be demonstrated, the situated knowledge thesis still implies that members of marginalized and oppressed groups should be given a hearing in the collective production of knowledge for epistemological and not just ethical reasons.

Deterrence

Abstract

Although the idea of threatening war to prevent war is as old as the balance of power, deterrence is not just a new word for that old idea but a new idea spawned by the nuclear age. Deterrence means threatening with punitive retaliation to prevent a foe from attacking. It differs fundamentally from defense, which means threatening to fight back if attacked and deny an attacker its objectives. To deter nuclear attack, it is deemed necessary to threaten nuclear retaliation. The prohibitive cost of a nuclear war keeps either side from risking it. Yet that rational calculus overlooks the irrationality of retaliating for a nuclear first strike with a nuclear second strike against a well-armed attacker. Moreover, military plans in practice do not resemble deterrence in theory. The enormous advantage of striking first has prompted the United States and the Soviet Union, now Russia, to keep forces on hair-trigger alert, raising fear of loss of nuclear control in a crisis. As a consequence, while some saw mutual deterrence as a source of stability, others saw it as extremely unstable, leading them to renewed appreciation of the security dilemma, where attempts to enhance or demonstrate military were self-defeating, and safety lay in cooperation between enemies.

Deterrence means threatening with punitive retaliation to prevent a foe from attacking. It differs fundamentally from defense, which means threatening to fight back if attacked and deny an attacker its objectives. The heart of the distinction is whether it would make sense to carry out the threat.

Although the idea of threatening war to prevent war is as old as the balance of power, deterrence is not just a new word for that old idea. The idea of deterrence originated with the atomic bomb. It was first formulated in 1946 by Bernard Brodie, who tried to capture what was revolutionary about the advent of the nuclear era. First, a nuclear warhead was not a weapon, in Brodie's view, but a terrorist device, whose blast and radiation effects made it inherently indiscriminate. Second, the atomic bomb brought home the fact of mutual vulnerability in a way that aerial bombardment had not. Before the nuclear era, a state's armed forces had to be defeated before the state and its centers of population could be held hostage or destroyed at will. Once nuclear warheads were mated to missiles in the late 1950s, the state and its populace were defenseless. The balance of terror differed in fundamental respects from the prenuclear balance of power, according to Brodie. "The first and most vital step," he wrote, "for the age of atomic bombs is to take measures to guarantee ourselves in case of attack the means of retaliation. Thus far the chief purpose of a military establishment has been to win wars. From now on its chief purpose must be to avert them." These prescient insights became a matter of considerable scholarly discourse. Regrettably they had little influence on nuclear policy.

Deterrence in Theory

The logic of deterrence, as Brodie and others recognized, is inherently paradoxical. To deter nuclear attack, it is deemed necessary to threaten nuclear retaliation. Inasmuch as the cost of a nuclear war is prohibitive, neither side would risk it. Yet that rational calculus conveniently overlooks the irrationality of retaliating for a nuclear first strike with a nuclear second strike. Retaliation makes no sense unless the second strike could eliminate the other side's nuclear forces and prevent it from launching another strike of its own. That deadly logic led Brodie to the paradoxical conclusion that what made deterrence work was the possibility that it might fail, making it prudent for neither side to tempt fate. The same logic led other strategic thinkers to conclude that for deterrence to work, it could not be mere bluff. The threatener had to be willing to carry out the threat. For that to happen, nuclear retaliation had to be automatic or mad. Herman Kahn (1960) captured the sense of that line of reasoning in a phrase, the 'rationality of irrationality.' Yet that line of reasoning only posed another paradox: if the deterrer was hotheaded, why would the attacker be prudent?

Even if the threat of retaliation ruled out nuclear war, that seemed to leave the world safe for war waged by other than nuclear means. That was a source of gnawing anxiety for the USA, which was committed by a treaty to deter any attack by the USSR on its allies in Western Europe. It did not have the capability to do that by conventional military means alone, at least in the 1950s, so it chose to rely on the threat to initiate nuclear war. That threat was potentially suicidal.

Some strategists insisted that 'extended deterrence,' as that threat came to be called, would work if the USA had nuclear superiority. Thomas Schelling (1966) questioned whether superiority assured that the weaker side must yield to the stronger. It was impossible, he insisted, to raise the risk of a nuclear war for the other side without raising it for oneself. He spoke, instead, of a 'competition in risk-taking.' Extended deterrence still might work if the Soviet leaders could not be sure the USA would shrink from first use of nuclear weapons in the event of war. Schelling (1960) called it 'the threat that leaves something to chance.' Such a cosmic bluff prompted a preoccupation with 'credibility' and a willingness to run seemingly irrational risks to shore up an incredible threat. McGeorge Bundy (1983) came up with a less demanding alternative, 'existential deterrence.' So long as a state possessed nuclear arms, Bundy argued, it had a latent ability to use them,

even if it did not explicitly threaten to do so. The mere existence of these arms and the incalculable costs of a nuclear war exerted a cautionary effect on potential foes.

Other strategic thinkers took a more forceful tack. British strategist Basil Liddell Hart (1946) first formulated the idea of graduated deterrence, carefully calibrated to threaten greater costs to an attacker without generating all-out war. Still others debated whether military forces or civilians were the most appropriate targets for nuclear attack. This line of thought culminated in the baroque escalation ladder of Herman Kahn (1960) and the contention of some of his followers that the USA could deter any aggression if it somehow had 'escalation dominance,' or military superiority at every level of violence, short of an all-out nuclear war. Yet the idea of waging limited nuclear war and controlling escalation raised the question of how a nuclear war could stop, short of a dead end.

Deterrence in Practice

Deterrence, in short, did not work very well in theory. What happened in practice was in many ways worse. Deterrence did not govern the production, deployment, or military plans for nuclear arms (Ball, 1980). The number of the Soviet and the US warheads vastly exceeded what was needed for deterrence. The warheads themselves were initially deployed in ways that made them vulnerable to attack. Dispersing them on land and at sea reduced, though did not eliminate their vulnerability, and made command-and-control all the more precarious. Because of the chance that the cosmic bluff could be called, each side drew up detailed war plans to destroy the other. Those war plans fully reflect the deadly logic of deterrence: in the event that war breaks out, nuclear arms confer enormous, some say decisive, advantage on the side that strikes first. The most urgent targets were the other side's nuclear forces and especially their command-and-control. Concern about a disarming first strike led the USA to keep some of its bombers airborne at all times and to put others on alert, ready to take off at a moment's notice. It did the same with its missiles. This hair-trigger posture, and the delegation of authority that it necessitated, raised the risk of loss of nuclear control in a crisis. Schelling (1960) called this predicament 'the reciprocal fear of surprise attack.' As first one side and then the other began mobilizing forces, the very steps taken to deter a nuclear war might provoke one. Far from exerting a cautionary effect on preparations for war, that fear led both sides to a massive buildup of arms, conventional as well as nuclear, which did little to calm the fear.

That had important implications for theorizing about deterrence. Although some theorists saw mutual deterrence as a source of stability in international politics, others saw it as potentially unstable in the extreme. The first group emphasized the need to demonstrate the capability and will to wage war, lest a potential aggressor doubt a state's strength or resolve. By this way of thinking, conciliation was dangerous because it might be mistaken for weakness or irresoluteness. A second group of theorists were led to a renewed appreciation of the security dilemma, an idea dating back to Thucydides, who noted that attempts by one side to enhance or demonstrate its military might prove self-defeating. By alarming its rival and leading it to respond in kind, these measures would leave both sides less secure. Such a vicious circle could generate an arms race, or worse, trigger preemptive war. These theorists saw the need to couple coercion with conciliation, lest the interaction spiral out of control. To some scholars, the difference between the deterrence and spiral logic depended on each side's perception of the other's intentions.

Where perception matters, so does the danger of misperception. The fear that war is imminent is sometimes irrational. Once it takes hold, it is not amenable to a cool calculation of costs. The possibility of preemptive war calls into question two major premises of most theorizing about nuclear deterrence, that statesmen will behave rationally in the heat of the moment and that they can control the operations of their armed forces. The questioning seems all the more pertinent with the proliferation of nuclear arms to states like Pakistan and North Korea or the risk that terrorists could get their hands on a nuclear weapon. This led to critiques of deterrence theory on the grounds that it was psychologically naive and operationally uninformed. Robert Jervis (1976), John Steinbruner (1974), and Scott Sagan (1993) are leading exemplars of these approaches.

One side's strategy depended on the other's. So did its security. Their interdependence was the central feature of *game theory*. Whether the game of chicken or the prisoner's dilemma was the appropriate analogy, many scholars who formulated the logic of deterrence drew heavily on game theory for their insights.

One consequence is that deterrence is largely deductive and only weakly grounded empirically. Another reason for its weak evidentiary base is that nuclear history everywhere remains cloaked in secrecy. Without knowledge of the details of nuclear planning and operations, it is difficult to determine how much nuclear strategy is informed by deterrence theory, if at all. A more fundamental reason why the evidence for deterrence is less than compelling is the epistemological difficulty of proving why something did not happen in order to demonstrate that deterrence worked. The obvious counter to the contention that nuclear deterrence kept the USSR out of Western Europe is that it never intended to invade in the first place.

Because the side that is losing could still destroy the side that is winning, safety in the nuclear era lay in cooperation between enemies. That interdependence made nonsense of traditional strategic thought. It also called into question the very idea of strategy as a rational relationship between means and ends. War, in theory, if not always in practice, "is controlled by its political object," Clausewitz had reasoned. Consequently, "the value of this object must determine the sacrifices to be made for it in magnitude and also duration." But what objective could possibly sustain the full measure of sacrifice in a nuclear war? As Lawrence Freedman (1981) concludes, "The position we have reached is one where stability depends on something that is more the antithesis of strategy than its apotheosis – on threats that things will get out of hand, that we might act irrationally, that possibly through inadvertence we could set in motion a process that in its development and conclusion would be beyond human control and comprehension." Nuclear strategy, understood this way, was a contradiction in terms.

Deterrence: Sanction Perceptions

Robert Apel, Rutgers University, Newark, NJ, USA

Abstract

This article conducts a survey of theory and research concerning the determinants of an individual's perceptions of the risk of formal sanctions as a consequence of criminal behavior. The specific questions considered are as follows: (1) How accurate is people's knowledge about criminal sanctions? (2) What is the impact of risk perceptions on the likelihood of criminal behavior? (3) What is the impact of criminal experience on the modification of risk perceptions?

Overview

Decisions about participation in criminal behavior involve forming expectations about the future. These expectations concern the potential rewards as well as the potential harms of criminal actions. The potential rewards associated with crime are largely pecuniary (i.e., the 'loot'), but they may also entail reputational rewards (e.g., peer approval) and psychic rewards (e.g., thrill). The potential harms of crime encompass bodily harm (e.g., injury if a victim resists), medical harm (e.g., disease from sharing drug needles), and psychic harm (e.g., pangs of conscience). Most importantly for present purposes, the potential harms also include legal harms, which involve restrictions on personal freedom, such as a fine, an arrest, or confinement in a jail or prison. Moreover, because the legal consequences of crime are uncertain, would-be offenders must form assessments of the probability and magnitude of criminal sanctions. Sanction perceptions refer to a would-be offender's estimate of the likelihood of being detected, arrested, convicted, and incarcerated upon committing an offense (perceived sanction certainty), as well as the length of the custodial sentence or the strictness of the supervisory conditions imposed upon conviction (perceived sanction severity).

Modern criminological interest in the study of sanction perceptions arose in the 1970s and 1980s as researchers sought to more clearly delineate the link between criminal punishments and individual criminal behavior. From this interest arose a tradition of research in perceptual deterrence. Scholars observed that criminal deterrence is fundamentally a process of information transmission. It is intended to discourage law violation by communicating to potential law violators the punishments that might arise when they violate legal proscriptions. Indeed, Nagin (1998: p. 18) observes that "behavior is immune to policy manipulation" to the degree that there is no link between policy and perceptions. Three distinct research strategies can be discerned in the perceptual deterrence tradition, and these are the subjects of this article (for more in-depth review, see Apel, 2013). These include the accuracy of sanction risk perceptions, the deterrent effect of risk perceptions on criminal behavior, and the experiential effect of criminal behavior on risk perceptions. Each will be reviewed in more detail below.

Accuracy of Sanction Risk Perceptions

One major perceptual deterrence research tradition entails estimating the degree of correspondence between area-level measures (usually the county) of criminal punishment and individual perceptions of sanction risk. These are known as calibration studies. In order for a sanction policy to influence behavior, individual perceptions of the certainty and severity of sanctions must have some grounding in reality. Consequently, the mean perceived sanction from a sample of respondents should be closely calibrated to the objective sanction of interest.

In 1967, the California Assembly commissioned a survey to determine how knowledgeable different groups of respondents were of the prevailing statutory penalties for criminal behavior (Assembly Committee on Criminal Procedure, 1968). The sample included over 1500 subjects and comprised noninstitutionalized civilians, college students, high school youth (stratified by low- and high-delinquency schools), institutionalized youth, and institutionalized adults. Of six offenses examined – assault with a deadly weapon, second degree burglary, first degree robbery, forcible rape, joy riding, fraudulent check writing – the percentage of respondents who identified the correct maximum penalty was 26% (these are manual calculations made by the authors based on information tabulated in the original report). The worst calibration was attained by the noninstitutionalized civilians and low-delinquency high school youth (22 and 23%, respectively), while the best calibration was attained by the institutionalized adults (62%). Among those who misjudged the maximum sentence, the predominant tendency was to underestimate the penalty.

The committee also inquired about public knowledge concerning legislative activity for three offenses whose penalties had recently increased (rape, robbery, and burglary) and two offenses whose penalties had not changed (marijuana possession and driving under the influence). The percentage of respondents who answered correctly about whether or not the penalties had recently changed was 28%. Again, the most knowledgeable subjects were the institutionalized adults, among whom 52% responded correctly. Among respondents who misjudged the legislative changes, the tendency was to report that the severity of the penalty had decreased or else

 http://dx.doi.org/10.1016/B978-0-08-097086-8.45041-5

to understate the magnitude of the penalty increase. The committee's conclusion concerning recent legislative changes was blunt: "While the Legislature had supposedly responded to public appeal and increased the penalties for crime of violence to victims, this was not known by the public" (Assembly Committee on Criminal Procedure, 1968: p. 14).

Kleck et al. (2005) conducted a telephone survey of about 1500 adults residing in 54 large urban counties in 1998, inquiring about respondents' perceptions of criminal punishment for four offenses in their county (homicide, robbery, burglary, and aggravated assault). The mean perceived arrest rates for homicide and assault underestimated the objective arrest rates, while the perceived arrest rates for robbery and burglary overestimated the objective arrest rates. Perceived incarceration probabilities (conditional on conviction), on the other hand, were consistently underestimated and considerably so.

Ross (1973) reported on the findings of a public opinion survey conducted before and after passage of the British Road Safety Act (BRSA) of 1967. The BRSA included a number of provisions: a fixed blood alcohol level was adopted as the legal definition of impairment, a field breath test followed by laboratory analysis of the motorist's blood or urine was to provide the evidence of impairment, and motorists were required to submit to a breath test when an officer had reasonable cause to suspect drunkenness or else face the same penalties as if they had failed the test (e.g., loss of driver's license and arrest). The British government also embarked on a large-scale campaign to inform the public about the provisions of the BRSA. In a public opinion survey intended to gauge the level of public awareness of the BRSA, the percentage of respondents who were aware of the blood alcohol limit increased from 22 to 39%. Furthermore, 99% of respondents knew that a breath test was the basis for prosecution and 95% knew that refusal of a breath test could lead to arrest.

MacCoun et al. (2009) pooled data from the National Survey on Drug Use and Health, limiting their attention to about 135 000 adults 18 years or older. Respondents were asked to report whether, to their knowledge, the maximum penalty in their state for first-time possession of an ounce or less of marijuana was a fine, probation, community service, possible prison sentence, or mandatory prison sentence. The authors then compiled information on each state's laws, classifying states by the exact statutory penalties assessed (e.g., fine amount, jail time, diversionary, and expungement provisions). Residents of states that decriminalized marijuana possession, compared to states in which marijuana possession was still criminalized, did indeed report significantly more lenient sanctions for violation, but the actual differences were surprisingly modest in substantive terms. For example, among residents of states with a decriminalization policy, 44% still reported that the maximum penalty included the possibility of a jail or prison sentence compared to 49% among residents of states without a decriminalization policy.

To summarize calibration studies, scholars have shown that survey respondents have a general tendency to overestimate arrest probabilities (sanction certainty) but to underestimate maximum penalties (sanction severity). Yet when respondents are asked about the statutory applicability of specific criminal penalties, there tends to be much stronger correspondence between perceptions and reality. Therefore, while the average citizen does a reasonable job of knowing what criminal penalties are statutorily allowed, she does a poor job of estimating the probability and magnitude of the penalties.

If people are only vaguely aware of criminal punishments, then the deterrence rationale of punishment is seriously undermined. Yet there is still much to be learned about how individuals calibrate their risk perceptions with respect to objective punishment likelihoods. For example, most people are not 'in the market' for the kinds of serious criminal offenses that have been the subject of many studies. In the language of deterrence, most survey respondents are not 'on the margin' for serious law-violating behavior – they are committed law abiders. Population-based studies are likely to be composed largely of committed law abiders, especially when serious crimes are under consideration, and consequently, there is no a priori reason to expect that their perceptions will be highly accurate. It is noteworthy that studies of criminal statutes concerning drunk driving and marijuana possession tend to provide more consistently favorable evidence for perceptual deterrence principles. One plausible reason for this is that these studies are concerned with offenses (alcohol and marijuana use) and populations (young people) that are actually 'deterrable' in the sense that many individuals are on the margin for these kinds of behaviors.

Furthermore, experience with drunk-driving legislation or enforcement highlights two perceptual deterrence weaknesses in practice. For one, many sanction changes concern 'downstream penalties' that increase sanction severity rather than sanction certainty. This distinction is relevant because perceptual deterrence research uniformly suggests that would-be offenders are more strongly deterred by the certainty of punishment than by the severity of punishment (see Nagin, 1998) not to mention that downstream penalties can be heavily discounted because of the inevitable delay in their implementation. In addition, the failure of criminal justice officials to carry through on punishment threats can undermine perceptual deterrence. Drunk-driving evaluations demonstrate that while downstream penalties are often harsher, as intended, 'upstream enforcement' is largely unchanged (e.g., Ross, 1973). Specifically, changes in drunk-driving policies do not materially alter police behavior and thus result in little change in the actual risk of apprehension. Even when citizens are knowledgeable about criminal penalties, therefore, the deterrence potential of sanctions can be significantly eroded when experience indicates that crime detection remains so improbable as to be ignorable, even when the sanctions are quite severe.

Deterrent Effect of Risk Perceptions on Criminal Behavior

Research on the deterrent effects of perceptions on unlawful behavior has proceeded along three distinctive methodological lines: cross-sectional surveys, panel studies, and vignette research. Cross-sectional surveys inquire about individuals' current perceptions of sanction risks (certainty and severity) and either their behavior within some reference period prior to the interview or alternatively their intentions to commit crime in the future. Panel studies are designed to untangle

temporal priority for the perceptions–behavior link that vexes cross-sectional research by relating perceptions in one period to actual behavior reported in a later period. While cross-sectional surveys consistently show that risk perceptions are inversely correlated with offending behavior, panel studies tend to reveal correlations that are substantially diminished (Paternoster, 1987).

Vignette research provides respondents with a detailed hypothetical crime scenario and then asks them about their perceptions of the certainty and severity of punishment for the crime as well as their own behavior if they found themselves in the same situation. A unique feature of this design is that situational characteristics can be experimentally manipulated in order to study how subjects respond to a variety of incentives, disincentives, and opportunity structures. For example, Nagin and Pogarsky (2001) presented to university students a scenario describing an incident of drunk driving in which potential punishments were experimentally manipulated. Respondents given a scenario with a longer length of license suspension (higher severity) reported a significantly lower likelihood of driving drunk, although this effect appeared to be diminished among individuals who were more present oriented or impulsive (i.e., those with a higher 'discount rate'). The authors also inquired about the subjects' own estimated likelihood of being apprehended and convicted for drunk driving (a measure of certainty) under the conditions described in the scenario and found that perceived certainty was a robust predictor of intentions to drive drunk.

Research on the perceptual deterrence has produced two other sets of findings that are important to understanding the sources of deterrence. The first concerns the comparative deterrent effects of the certainty and severity of punishment. The perceptual deterrence literature finds more consistent evidence of the certainty of punishment as a crime deterrent relative to the severity of punishment. The second concerns the role of informal sanctions in the deterrence process. Zimring and Hawkins (1973: p. 174) observe that formal punishment may best deter when it sets off informal sanctions: "Official actions can set off societal reactions that may provide potential offenders with more reason to avoid conviction than the officially imposed unpleasantness of punishment." This research has consistently found that individuals who report higher stakes in conventionality are more strongly deterred by their perceived risk of punishment for law breaking.

A salient example of research supporting the 'certainty principle' as well as untangling the link between formal and informal sanctions concerns tax evasion. In the United States, civil enforcement actions by tax authorities are a private matter unless the taxpayer appeals the action. Because tax authorities are scrupulous about maintaining the confidentially of tax return information, for civil enforcement actions, noncompliers are gambling only with their money and not their personal reputations. In Klepper and Nagin (1989), a sample of generally middle-class adults were posed a series of tax noncompliance scenarios. The scenarios laid out the essential features of a tax report – income from different sources, number of exemptions, and various deductions. They then experimentally varied the amount and type of noncompliance (e.g., overstating charitable deductions or understating business income) across tax return line items and found that a majority of respondents reported a nonzero probability of taking advantage of the noncompliance opportunity described in the scenario. Plainly, the respondents were generally willing to consider tax noncompliance when only their money was at risk. They also seemed to be calculating; the attractiveness of the tax noncompliance gamble was inversely related to the perceived risk of civil enforcement.

The one exception to the rule of confidentially of enforcement interventions is criminal prosecution. As with all criminal cases, criminal prosecutions for tax evasion are a matter of public record. Here, Klepper and Nagin found evidence of a different decision calculus – seemingly all that was necessary to deter evasion was the perception of a nonzero chance of criminal prosecution. Stated differently, if the evasion gamble also involved putting reputation and community standing at risk, the middle-class respondents were seemingly unwilling to consider taking the noncompliance gamble.

This finding helps explain why the certainty of punishment may be a greater deterrent than severity. If the social and economic costs of punishment are strictly proportional to the punishment received; for example, if the cost to the individual of a 2-year prison term is twice that of a 1-year sentence, certainty and severity will equally affect expected cost. This is because expected cost is simply the product of certainty, P, and severity, S. The value of the product, $P \times S$, is equally affected by proportional changes in P or S. For example, the impact on expected cost of a 50% increase in P is the same as a 50% increase in S. However, the Klepper and Nagin study suggests that people do not perceive that costs are proportional to potential punishment. Instead, it seems that they perceive there is fixed cost associated with merely being convicted or even apprehended if it is public record.

While Klepper and Nagin (1989) did not pin down the specific sources of these costs, other research on the impact of a criminal record on access to the legal labor market suggests a very real basis for the fear of stigmatization. For example, a prison record depresses the probability of employment by about 15%. More recent studies reinforce these earlier findings. Western (2002) estimates the wage reduction effect of incarceration to be about 16%. He also finds that incarceration deflects individuals onto a flatter wage trajectory in which wage growth is slowed by 31% relative to comparably high-risk men who were not incarcerated. Pager (2003) reports that employers advertising entry-level job openings were less than half as likely to call back applicants who reported a criminal history (a felony cocaine trafficking conviction with 18-months prison time). Her conclusion is that "criminal records close doors in employment situations" (p. 956).

Experiential Effect of Criminal Behavior on Risk Perceptions

An early conclusion of perceptual deterrence researchers was that people's own experiences with crime and punishment were more salient determinants of their risk perceptions than external sources of information about sanction risk. Perceptual deterrence research also found that individuals who have experience as criminal offenders tended to have substantially lower risk perceptions, and therefore, more accurate risk

perceptions, compared to individuals who lack such experience. This begs the question of whether offenders' lower risk perceptions might be a consequence of their criminal behavior as well as a cause. Panel studies of the deterrent effect of perceptions were conducted to speak to this question. The first wave of such studies indicated that there is a pronounced experiential effect of delinquent or criminal behavior on risk perceptions (Paternoster et al., 1982). Furthermore, among active offenders, the experience of being sanctioned (and sanctioned more severely) itself contributes to an increase in risk perceptions (Apospori and Alpert, 1993). There are also compelling reasons to believe that individuals change their risk perceptions, in part, on the basis of the crime and punishment experiences of their friends and family members. Stafford and Warr (1993) refer to such effects as indirect or vicarious experiences.

Another important determinant of risk perceptions in addition to personal and vicarious punishment experience, according to Stafford and Warr (1993), is personal and vicarious punishment avoidance. There is evidence from a number of studies that, other things equal, a higher level of unsanctioned offending lowers one's perceptions of formal sanction risk. For example, in a study by Horney and Marshall (1992), offenders with higher 'arrest ratios' (i.e., more reported arrests per reported offenses) had higher perceptions of the risk of detection. Stated differently, offenders with more unsanctioned offenses – that is, more successful criminal careers, with success defined as avoidance of arrest – had lower risk perceptions.

These findings on the experiential effects of punishment and behavior on risk perceptions have spawned a second-generation research tradition concerned with the development and testing of formal models of change in risk perceptions as a consequence of personal and vicarious experiences with, and avoidances of, arrest and punishment (e.g., Anwar and Loughran, 2011; Matsueda et al., 2006). Many of these studies appeal to a Bayesian model of learning. A Bayesian model of risk perceptions and criminal behavior begins with an individual's initial assessment of the likelihood of apprehension for criminal conduct. This is known as the 'prior probability' of the risk of arrest (among other sanctions). The perceptual deterrence literature strongly suggests that the prior probability estimates of individuals without offending experience systematically and often substantially overstate the true risk of apprehension. Over time, the individual will accumulate personal and/or vicarious experiences as a successful or unsuccessful criminal offender. Note the parallel with Stafford and Warr's (1993) conceptualization of personal and vicarious punishment experience and punishment avoidance. The expectation is that the individual will then 'update' his or her assessment of the risk of apprehension based on these experiences. The resulting 'posterior probability' of the risk of arrest is a weighted sum of the individual's prior probability and the new information.

Anwar and Loughran (2011) have significantly advanced empirical testing of the Bayesian updating model by looking for more fine-grained predictions of it. First, they observe that the effect of arrest within a reference window should depend on the number of crimes committed during that period. For example, being arrested once should matter more for an offender who committed only one crime as opposed to an offender who committed 10 crimes. In the case of the former, the 'experienced arrest certainty' is 100%, whereas in the case of the latter, it is only 10%. Second, Anwar and Loughran observe that the effect of arrest should diminish as individuals gain more offending experience. In other words, since posterior risk perceptions are a function of prior risk perceptions and new information in the form of their arrest ratio (what they refer to as a 'signal'), experienced offenders should place more weight on their prior risk perceptions in the sense that they should update less in response to new information simply because they have more experience upon which to draw. Inexperienced offenders, on the other hand, should update more to bring their risk perceptions closer in line with their actual punishment risk. Third, Anwar and Loughran observe that the effect of arrest should be crime specific or at least specific within a class of criminal behaviors. That is, an arrest for a violent crime should influence risk perceptions of violent crime only and not risk perceptions of property crime. All three of these predictions were tested and supported from a sample of serious juvenile offenders.

Conclusions

Research on criminal sanctions indicates quite clearly that punishment has a substantial deterrent effect on criminal behavior (Apel and Nagin, 2011). However, devising sensible deterrence-based crime policies requires much better knowledge of the determinants of sanction risk perceptions. In recent years, greater attention has been devoted to analyzing the linkage of sanction risk perceptions to policy and to personal and vicarious experiences with the criminal justice enforcement apparatus. The Bayesian learning model provides a valuable theoretical structure for organizing and building on this research. Given the theoretical significance of sanction risk perceptions, and the policy significance of planful efforts to manipulate them, filling the existing empirical gaps should be a high priority for criminological scholars.

Deterrence Theory: Crime

Abstract

Deterrence theory can be traced to the early utilitarian philosophers, Cesare Beccaria and Jeremy Bentham, who believed that people are motivated to obtain pleasure and avoid pain. Crime, then, can be deterred by increasing the certainty (likelihood), celerity (swiftness), and severity (amount) of legal punishment for committing it. That idea continues to form the basis for contemporary deterrence theory, and that theory is subsumable under the more general social learning and rational choice theories. Contemporary deterrence theorists have recognized several important complexities, including distinctions between specific and general deterrence, absolute and restrictive deterrence, and actual and perceived punishments. Moreover, they have recognized that the deterrent effects of legal punishment may be contingent on a host of other factors, including the threat of extralegal punishment.

Introduction

The word *deterrence* has been linked to different topics, including nuclear deterrence (see *Oxford English Dictionary*), but the focus here is on how legal punishments deter crime. Defined simply, criminal deterrence is the omission or curtailment of crime out of fear of legal punishment.

An early version of deterrence theory was proposed by the utilitarian philosophers Cesare Beccaria (1738–94) and Jeremy Bentham (1748–1832), who believed that people will seek to maximize the pleasurable consequences (rewards) and minimize the painful consequences (punishments) of their behavior (principle of hedonism). To the extent that people anticipate pleasure from crime, they can be deterred by making its consequences more painful. This can be accomplished by making legal punishments more *certain*, *celeritous*, and *severe*. *Certainty* refers to the likelihood of being caught and legally punished for a crime; *celerity* is the swiftness of legal punishment; and *severity* is the amount of legal punishment (Durlauf and Nagin, 2011; Pratt et al., 2006). The ideas proposed by Beccaria and Bentham can be reduced to one concise statement: "The rate for a particular type of crime … [should vary] inversely [negatively] with the celerity, certainty, and severity of punishments of that type of crime" (Gibbs, 1975: p. 5).

Deterrence depends on the interplay of certainty, celerity, and severity. For example, "no level of severity will deter when no prospect of actual punishment is present … [i.e., certainty must be greater than 0] just as certain punishment … will not deter without severity [i.e., severity must be greater than 0]" (Durlauf and Nagin, 2011: p. 17). However, this does not mean that certainty and severity are equally important in deterring crime. There is considerable evidence that the deterrent effects of legal punishment are stronger for certainty than severity (Nagin and Pogarsky, 2001; Paternoster, 2010), and the reason may have to do with the low celerity of severe legal punishments. They often commence long after a crime has been committed and are experienced over a lengthy period (e.g., long prison sentences). According to Beccaria and Bentham, delayed legal punishments reduce punishment severity. "In economics, the concept of discounting is used to explain why future [delayed] consequences might be given less weight than present consequences" (Durlauf and Nagin, 2011: p. 17), and criminal offenders might be prone to greater discounting than other people.

Complexities

Several complexities need to be considered, one of which has to do with the distinction between *specific* and *general* deterrence (Stafford and Warr, 1993). Whereas *specific deterrence* refers to the deterrent effects of directly experiencing a legal punishment, *general deterrence* refers to the deterrent effects of indirectly experiencing it. Thus, when a person is imprisoned for committing a burglary and later is released, the imprisonment deters *specifically* to the extent the released burglar refrains from burglary (and possibly other types of crime as well) out of fear of additional imprisonment. If people other than the imprisoned burglar learn about the imprisonment and refrain from committing the same crime (or other types of crime) out of fear of it happening to them, they have been *generally* deterred. The distinction is important because a given legal punishment, such as imprisonment, could deter only *specifically* or only *generally*, instead of both. The exception is the death penalty, which can deter only generally, if at all. Executed offenders do not refrain from crime out of fear of legal punishment; they are incapacitated rather than specifically deterred.

It may seem that the commission of a crime is itself negative evidence for deterrence. For example, it sometimes is argued in reference to U.S. criminal justice policy that threatens illegal drug users with imprisonment that continued drug use signals the threat of imprisonment did not deter. However, the argument ignores the distinction between *absolute* and *restrictive* deterrence, which are notions that correspond with the words *omission* and *curtailment*, respectively, in the definition of criminal deterrence above (Gibbs, 1975: pp. 32–34). To the extent that people refrain completely from committing a crime (i.e., omission of crime) out of fear of legal punishment, they are deterred *absolutely*. However, they may not be deterred absolutely, but, instead, be deterred *restrictively* by curtailing or limiting the amount of crime they commit, as when people

limit their illegal drug use to reduce their risk of legal punishment, possibly out of a sense of cumulative risk. With restrictive deterrence, the key question is how much crime would occur if there were either no or less threatened legal punishment for it, not whether crimes would occur at all.

Three Central Premises of Deterrence Theory

According to Gibbs (1975), there are three central premises of deterrence theory:

1. The greater the actual certainty, celerity, and severity of legal punishment, the greater the perceived certainty, celerity, and severity of legal punishment.
2. The greater the perceived certainty, celerity and severity of legal punishment, the less the likelihood of crime.
3. The greater the actual certainty, celerity, and severity of legal punishment, the less the likelihood of crime.

Or stated diagrammatically: AP < - > PP > - < CR, where AP denotes actual punishments, PP denotes perceived punishments, CR denotes crime, the symbol < - > denotes a positive relationship, and > - < denotes a negative relationship.

In contrast to the actual certainty, celerity, and severity of legal punishment in a given time and place for a given type of crime, perceived punishments pertain to people's perceptions of the certainty, celerity, and severity of legal punishment for the same crime in the same time and place (Pratt et al., 2006). For example, if the actual certainty of arrest for burglary in a particular U.S. state in a given year is 25% (police make 25 arrests for every 100 burglaries committed), people may perceive the certainty of arrest for burglary to be 25%, or they may perceive it to be higher or lower than 25%. Although the example allows for the possibility of error (over- and underestimation) in people's perceptions of punishment (Paternoster, 2010: p. 785), deterrence theorists since Beccaria and Bentham have assumed there is a strong positive relationship between actual and perceived punishments (Premise 1), and that assumption is important for two reasons. First, "to the extent that changes in actual penal policies do not alter potential offenders' beliefs about the likelihood or severity [or celerity] of punishment, they cannot generate any … deterrence" (Von Hirsch et al., 1999: p. 6). Second, demonstration of a positive relationship between actual and perceived legal punishments is crucial in distinguishing deterrence from other possible preventive consequences of legal punishment. To illustrate, suppose there is a strong negative relationship among U.S. states between the actual certainty of imprisonment for auto theft and the auto theft rate (as would be predicted by Premise 3 above). It may not be fear of legal punishment (deterrence) that accounts for the relatively low auto theft rate in states with a high certainty of imprisonment for auto theft. There are few, if any, opportunities to commit auto theft in prison, so the imprisonment of large numbers of auto thieves, especially high-rate auto thieves, could cause a low auto theft rate through *incapacitation* rather than deterrence. There would be evidence of deterrence only to the extent that people in states with a high actual certainty of imprisonment for auto theft perceived it to be high (Premise 1) and there were low auto theft rates in states with high actual certainty of imprisonment for auto theft (Premise 3) and high perceived certainty of imprisonment for auto theft (Premise 2).

Conditions

There are many conditions under which the certainty, celerity, and severity of legal punishments deter to a greater or lesser degree, and any discussion of deterrence theory must consider them (Tittle et al., 2010: p. 1042). One such condition already has been briefly considered – that the deterrent effects of a particular property of punishment, say certainty, depend on the level of another property of punishment, say severity. In one of the earliest empirical studies of deterrence, Tittle (1969: p. 7) examined the relationship among U.S. states between the actual certainty and severity of imprisonment and rates for seven crime types (e.g., homicide) and found that the actual severity of imprisonment "acted as a deterrent only when there was a high [actual] certainty of imprisonment." In contrast, actual certainty was negatively associated with the crime rates (i.e., the greater the actual certainty, the less the crime rate) regardless of the level of actual severity. Soon after publication of the Tittle study, Grasmick and Bryjak (1980) found in a study of the relationship among individuals between the perceived certainty and severity of punishment and self-reported crime that perceived certainty had stronger deterrent effects at higher levels of perceived severity and also that perceived severity had stronger deterrent effects at higher levels of perceived certainty.

The Grasmick–Bryjak study was particularly noteworthy at the time because of its focus on *perceived* certainty and severity. Recognizing problems in separating the effects of deterrence from incapacitation in studies like that of Tittle, scholars after the early 1980s increasingly believed that deterrence is mainly a psychological theory about individuals' perceived punishments. The prevailing belief became that actual "properties of punishment are important … only because they affect crime through individual perceptions" (Paternoster, 2010: p. 780).

Compared to research on perceived certainty and severity, there has been less research on the perceived celerity of legal punishments, and this includes whether it conditions the deterrent effects of perceived certainty and severity on crime. Nagin and Pogarsky (2001) reported no evidence that threat of delayed legal punishments (low celerity) conditioned the deterrent effects of either perceived certainty or severity on the likelihood of drinking and driving. Both perceived certainty and severity were negatively associated with drinking and driving, but there was no systematic association between it and celerity.

There is some evidence that the deterrent effects of the perceived certainty of legal punishment depend on the level of perceived certainty itself, that there is a nonlinear relationship between perceived certainty and crime. Loughran et al. (2012) have studied youth between ages 14 and 17, who were convicted of a serious crime either in juvenile or adult court. At 6-month intervals over a 36-month period, they were asked how likely was it was "they would be caught and arrested for … : fighting, robbery with gun, stabbing someone, breaking into

a store or home, stealing clothes from a store, vandalism, and auto theft" (p. 723). They also were asked to self-report whether they committed any of 17 crimes that were roughly equivalent to those in the perceived certainty questions. There was clear evidence of a nonlinear relationship. There was no deterrent effect of perceived certainty on a composite scale of the 17 crimes when it was below a tipping point – a perceived certainty value of about 0.3. When perceived certainty was between 0.3 and 0.9, a "10 percent increase in [perceived] risk [was] associated with a … 3.2% percent reduction in the probability of offending" (Loughran et al., 2012: p. 731). However, when perceived certainty was 0.9 or higher, reduction in the probability of offending was over four times greater – 13.3%. Thus, it appears that potential offenders are inattentive to the perceived certainty of legal punishment when it is below a certain threshold, and they may be very attentive when it seems a near certainty they will be caught and punished for committing a crime.

Additional Conditions

A long-held belief about deterrence is that some people are more deterrable than others because of their individual or group characteristics, and there is mounting evidence about what these characteristics are (Jacobs, 2010). Matthews and Agnew (2008: p. 96) have reported that high perceived certainty of detection by the police was less likely to deter crime among high-school students with delinquent peers because they were "more likely to (1) be rewarded for engaging in crime, (2) be sanctioned for *not* engaging in crime, (3) view the consequences of detection as less threatening, (4) temporarily reduce their perceived certainty of detection, and/or (5) give less thought to the likelihood of detection." Moreover, Tittle et al. (2011) have found that legal punishments are more likely to deter citizens of some nations than others – Russians and Ukrainians more than Greeks, seemingly because Greeks are less likely to contemplate committing crime.

There are many reasons why people do not contemplate committing crime, but one of the most important is morality (Tittle et al., 2010). Many conform to the law because they believe it is the morally right thing to do; for them, threats of legal punishment and deterrence are irrelevant. Empirical research has borne this out; for example, Bachman et al. (1992) indicated that perceived punishments for sexual assault reduced the likelihood of committing it, but only among those whose moral condemnation of sexually aggressive behavior was weak.

One of the most widely researched questions about deterrence is whether the deterrent effects of legal punishments depend on self-control (Piquero et al., 2011). People with low self-control have been characterized as impulsive risk takers with a present rather than a future orientation and, consequently, should be less deterrable than persons with high self-control (Gottfredson and Hirschi, 1990). While plausible, there is considerable negative evidence. Wright et al. (2004) found greater deterrent effects of punishment among persons with *low* self-control, and neither Tittle and Botchkovar (2005) nor Gallupe and Baron (2010) reported any moderating effect of self-control on deterrence.

Role of Extralegal Punishments in Deterrence

Although criminal deterrence, by definition, involves imposition of legal punishments, Williams and Hawkins (1986) have pointed out that deterrence also can involve extralegal punishments. To illustrate, while people may be deterred from committing a crime out of fear of being fined (a legally imposed economic loss) or imprisoned (a legally imposed deprivation of liberty), they also may refrain from crime because they fear extralegal punishments that may result from being caught as when some people lose their jobs after criminal convictions. Hence, extralegal punishments may be important to deterrence theory.

Nagin's (1998) study of tax evasion further illustrates the point. He found that there was at least some chance that middle-class persons would cheat on their taxes if enforcement was limited to threat of civil fines. However, there was no chance of cheating if enforcement put their "reputation and community standing at stake" (p. 352). Hence, legal punishments deterred best when tied to extralegal punishments.

In some cases, extralegal punishments may prevent crime only because they are linked to threat of legal punishments. In that connection, Williams and Hawkins (1992) examined the extent to which self-reported wife assault was affected by (1) perceived assault costs and (2) the perceived indirect costs of arrest. Perceived assault costs were measured by men's perceptions of the likelihood of losing (1) a spouse/partner, (2) respect of friends/relatives, and (3) self-respect for committing wife assault. Perceived assault costs were linked only to assault itself, not arrest. The perceived indirect costs of arrest included the same types of losses (e.g., losing a spouse/partner), but they could be triggered by arrest (e.g., survey respondents were asked about the chances of losing the respect of their friends if they were arrested for hitting their spouses or partners). A composite scale of the perceived indirect costs of arrest had a significant negative effect on men's self-reported wife assault, but there was no such effect for perceived assault costs that were not linked to arrest.

The deterrent effects of legal punishment also may depend on the possibility of extralegal punishments. Legal punishments may deter best among persons with the most to lose in the way of extralegal punishments for crime (Piquero et al., 2011). Williams and Hawkins (1986: p. 566) have offered this prediction: "the greater the perceived costs of … [a crime], the greater should be the negative effects of perceptions of certainty [of arrest] on the incidence of crime."

That prediction was supported by results from the famous domestic violence experiments conducted by Sherman and his colleagues. In one such experiment in Milwaukee, Sherman et al. (1992) randomly determined whether 1200 suspected domestic batterers would be arrested or warned by the police without an arrest. They, then, compared rates of new domestic violence by the two groups. Overall, arrest was no more effective than a police warning in decreasing new violence. However, absence of an overall arrest effect concealed a more complex pattern. While arrest decreased new violence among married and employed persons, it increased new violence among the unmarried and unemployed. These findings suggested to Sherman and his colleagues that "the effectiveness of legal sanctions rests on a foundation of informal control

[i.e., extralegal punishments]" (p. 688). Married and employed persons had more to lose in the way of extralegal punishments for domestic violence. Unmarried and unemployed batterers did not perceive police intervention as legitimate and "displaced [their anger about being arrested by the police] onto their present or future romantic partners or other citizens" (Sherman, 1993: p. 465). According to Sherman (1993: p. 460), legal punishments provoke "defiance" (i.e., persistent or more serious crime) to the extent offenders (1) perceive the punishment as unfair, (2) are weakly bonded to other community members, (3) perceive the punishment as stigmatizing, and (4) deny the shame associated with it.

The findings of Sherman et al. (1992) have been partially corroborated by Wooldredge and Thistlethwaite (2002) in a nonexperimental study of persons arrested for misdemeanor partner violence in Ohio. Consistent with the Sherman et al. findings, prosecuted offenders undergoing counseling had lower rearrest rates than arrested offenders who had no charges filed against them if they were more educated and residentially stable (same residence for five or more years). Moreover, probation or jail produced lower rearrest rates if sentenced offenders lived in neighborhoods with greater residentially stability. More educated and residentially stable people have more to lose than other sentenced offenders in the way of extralegal punishments, as do people who live in residentially stable neighborhoods "because of the possible stigma faced" for being sentenced (Wooldredge and Thistlewaite, 2002: p. 49). More educated and residentially stable offenders were not more deterred if they were sentenced to probation or jail without counseling.

Links between Deterrence Theory and Other Theories

Deterrence theory can be linked to other, more general theories of human behavior. Akers (1990) has argued that deterrence theory is derivable from more general *social learning* or *behavioral* principles. "Threat of legal punishment is one source or indicator of aversive stimulus under the general concept of differential reinforcement (balance of rewarding and aversive stimuli)" (p. 658). Differential reinforcement refers to the overall balance of rewards and punishments for behaviors, including past, present, and future rewards and punishments. General deterrence is equivalent to observational/vicarious learning in social learning theory, which involves observations of other people and how their behavior is rewarded and punished; and specific deterrence is equivalent to experiential learning, which involves direct, personal experience with the rewards and punishments for behaviors (Stafford and Warr, 1993).

Both deterrence theory and social learning theory can be linked to *rational choice theory* in that both address the question of why people in certain situations *decide* or *choose* to engage in particular behaviors (Akers, 1990; Paternoster, 2010). However, the meaning of "rational" is ambiguous. To some deterrence researchers, rationality implies conscious and deliberate calculations about the rewards and punishments for crime (e.g., Bachman et al., 1992; Wikstrom, 2008). Others deny that overt mental calculations of any kind are necessarily involved (e.g., Casey and Scholz, 1991). Moreover, rational choices are sometimes conceived as willful rather than determined (e.g., Bachman et al., 1992), but Cornish and Clarke (1986: p. 13) have argued that the "rational choice perspective is neutral with respect to the free will-determinism debate."

Disagreement about the meaning of the word "rational" stems from the existence of different versions of rational choice theory: old rational choice theory and new rational choice theory, each with different assumptions about rationality (Felson, 1993). Old rational choice theory, as set forth by such utilitarian philosophers as Beccaria and Bentham assumed that people engage in conscious and deliberate cost–benefit analysis to maximize the rewards and minimize the punishments for their behavior. The new version of rational choice theory entails weaker assumptions about rationality – that people intuit the rewards and punishments for a behavior and that they are imperfect processors of information and consequently must behave within the limits of their abilities to pursue what they perceive as most satisfying (e.g., Cornish and Clarke, 1986). The assumption of "maximizing" is rejected and replaced by alternative assumptions, such as "satisficing" and "bounded" or "situated" rationality. As for the issue of free will vs determinism, new rational choice theory posits that "people make choices, but they cannot choose the choices available to them" (Felson, 1986: p. 119).

Like new rational choice theory, deterrence theory does not require a strong assumption about rationality. In particular, crime need not be preconceived or carefully planned for legal punishments to deter, only that potential offenders choose between crime and conformity to the law on the basis of the rewards and punishments involved. Also, like new rational choice theory, deterrence theory does not require that people have free will. Indeed, a negative relationship between properties of legal punishment (e.g., the perceived certainty of legal punishment) and crime is as compatible with a strictly deterministic conception of human behavior as it is with free will (Gibbs, 1975: p. 24).

Abstract

This article reviews the evidence on the deterrent effect of police and imprisonment. Studies of changes in police presences, whether achieved by changes in police numbers or in their strategic deployment, consistently find evidence of deterrent effects. Studies of the deterrent effect of increases in already long prison sentences find at most a modest deterrent effect. Three high-priority areas for future research are identified: developing and testing an integrated model of the effects of the threat and experience of punishment, measuring perceptions of sanction regimes, developing and estimating the deterrent effect of shorter prison sentences and identifying high-deterrence policies.

Overview

The criminal justice system dispenses justice by apprehending, prosecuting, and punishing individuals who break the law. These activities may also prevent crime by three distinct mechanisms – incapacitation, specific deterrence, and general deterrence. Convicted offenders are often punished with imprisonment. Incapacitation refers to the crimes averted by their physical isolation during the period of their incarceration. Specific deterrence and general deterrence involve possible behavioral responses. Specific deterrence refers to the reduction in reoffending that is presumed to follow from the experience of actually being punished. However, there are many sound reasons for suspecting that the experience of punishment might instead increase reoffending. The threat of punishment might also discourage potential and actual criminals in the general public from committing crime. This effect is known as general deterrence and is the subject of this article.

Key Concepts of Deterrence

Deterrence is a theory of choice in which would-be offenders balance the benefits and costs of crime. Benefits may be pecuniary in the case of property crime but may also involve intangibles such as defending one's honor, expressing outrage, demonstrating dominance, cementing a reputation, or seeking a thrill. The potential costs of crime are comparably varied. For example, crime can entail personal risk if the victim resists, and it may also invoke pangs of conscience or shame. The theory of deterrence is predicated on the idea that if state-imposed sanction costs are sufficiently severe, criminal activity will be discouraged, at least for some. Thus, one of the key concepts of deterrence is the severity of punishment. The authors' review of severity effects focuses on research findings concerning imprisonment.

Severity alone, however, cannot deter. There must also be some possibility that the sanction will be incurred if the crime is committed. For that to happen, the offender must be apprehended, usually by the police. He must next be charged and successfully prosecuted, and finally sentenced by the judiciary. None of these successive stages in processing through the criminal justice system is certain. Thus, another key concept in deterrence theory is the certainty of punishment. In this regard, the most important set of actors are the police – absent detection and apprehension, there is no possibility of conviction or punishment. For this reason, the authors discuss separately what is known about the deterrent effect of police.

One of the key conclusions that emerged from the 1960s- and 1970s-era deterrence literature was that the certainty of punishment was a more powerful deterrent than the severity of punishment. The analyses of this era generally used cross-sectional data on states and involved testing the effects on the statewide crime rate of the certainty and severity of punishment, along with other demographic and socioeconomic control variables. The certainty of punishment was measured by the ratio of prison admissions to the number of reported crimes, while the severity of punishment was measured by median time served of recent prison releases. The basis for the 'certainty not severity' deterrence conclusion was that punishment certainty was consistently found to have a negative and significant association with the crime rate, whereas punishment severity generally had no significant association.

This conclusion at the time was probably based on faulty statistical inference. Two primary criticisms were leveled. The first was that the negative association between the certainty measure and crime rate was an artifact of the number of crimes appearing in the denominator of the certainty measure and the numerator of the crime rate. It can be mathematically demonstrated that errors in the measurement of number of crimes, of which there are many, will force a negative, deterrent-like association between the crime rate and certainty even if, in fact, the certainty of punishment had no deterrent effect on crime. The second involved the use of theoretically indefensible statistical methods for parsing out the cause–effect relationship between sanction levels and the crime rate. After all, sanctions may deter crime, but crime may also affect sanction levels. For example, perhaps overcrowded prisons might reduce the chances of newly caught offenders going to prison. However, subsequent findings from the so-called perceptual deterrence literature and economic studies of the effects of contact with

the criminal justice system on access to legal labor markets provide a far firmer empirical and theoretical basis for the 'certainty principle.' In order to focus on more recent research findings, this article will not cover these earlier research traditions.

The Deterrent Effect of Imprisonment

There have been two distinct waves of studies of the deterrent effect of imprisonment. As already noted, studies in the 1960s and 1970s examined the relationship of the crime rate to the certainty of punishment, measured by the ratio of prison admissions to reported crimes, and the severity of punishment as measured by median time served. These studies suffered from a number of serious statistical flaws that are detailed in Blumstein et al. (1978). In response to these deficiencies, a second generation of studies emerged in the 1990s. Unlike the first-generation studies, which primarily involved cross-sectional analyses of states, second-generation studies had a longitudinal component in which data were analyzed not only across states but also over time. Another important difference is that the second-generation studies did not attempt to estimate certainty and severity effects separately. Instead, they examined the relationship between the crime rate and rate of imprisonment as measured by prisoners per capita.

A review by Donohue (2007) identifies six such studies. All find statistically significant negative associations between imprisonment rates and crimes rates, implying a crime prevention effect of imprisonment. However, the magnitude of the estimate varied widely – from nil for a study that allowed for the possibility of diminishing returns, to an elasticity of −0.4. (By elasticities of 0.0 and −0.4, the authors mean that 10% growth in the imprisonment rate had either no effect on the crime rate or resulted in a substantial decline of 4%, respectively.) It is important to note that these studies are actually measuring a combination of deterrent and incapacitation effects. Thus, it is impossible to decipher the degree to which crime prevention is occurring because of a behavioral response by the population at large or because of the physical isolation of crime-prone people.

Donohue (2007) goes on to show that the small elasticity estimates imply that the current imprisonment rate is too large, while the high-end estimates imply the rate is too small. He lists a variety of technical shortcomings of these studies that, in our view, make it impossible to distinguish among the widely varying effect size estimates. The most important is the degree to which the studies were successful in separating cause from effect. While imprisonment prevents crime through a combination of deterrence and incapacitation, crime also generates the prison population. This is an example of what is called the "simultaneity problem," whereby one wants to ascertain the effect of one variable (the imprisonment rate) on another variable (the crime rate) in a circumstance where one knows or suspects that reverse causation is also present, namely, that the crime rate simultaneously affects the imprisonment rate. Thus, statistical isolation of the crime prevention effect requires properly accounting for the effect of crime on imprisonment. The Levitt (1996) study is arguably the most successful in this regard. It uses court-ordered prison releases as an instrument for untangling the cause-and-effect relationship. However, even the Levitt analysis suffers from many of the technical limitations detailed by Donohue.

More fundamentally, this literature suffers from more than just technical shortcomings that future research might strive to correct. It also suffers from important conceptual flaws that limit its usefulness in devising crime-control policy. Prison population is not a policy variable; rather, it is an outcome of sanction policies dictating who goes to prison and for how long, namely, the certainty and severity of punishment. In all incentive-based theories of criminal behavior, the deterrence response to sanction threats is posed in terms of the certainty and severity of punishment, not in terms of the imprisonment rate. Therefore, to predict how changes in certainty and severity might affect the crime rate requires knowledge of the relationship of the crime rate to certainty and severity as separate entities, which is not provided by the literature that analyzes the relationship of the crime rate to the imprisonment rate. The studies are also conducted at too global a level. There are good reasons for predicting differences in the crime reduction effects of different types of sanctions (e.g., mandatory minimums for repeat offenders versus prison diversion programs for first-time offenders). Obvious sources of heterogeneity in offender response include factors such as prior contact with the criminal justice system, demographic characteristics, and the mechanism by which sanction threats are communicated to their intended audience.

Three studies nicely illustrate heterogeneity in the deterrence response to the threat of imprisonment: the Weisburd et al. (2008) study on the use of imprisonment to enforce fine payment finds a substantial deterrent effect, the Helland and Tabarrok (2007) analysis of the deterrent effect of California's third strike provision finds only a modest deterrent effect, and the Lee and McCrary (2009) examination of the heightened threat of imprisonment that attends coming under the jurisdiction of the adult courts at the age of majority finds no deterrent effect.

Weisburd et al. (2008) report on a randomized field trial of alternative strategies for incentivizing the payment of court-ordered fines. The most salient finding involves the 'miracle of the cells,' namely, that the imminent threat of incarceration is a powerful incentive for paying delinquent fines. The miracle of the cells, the authors believe, provides a valuable vantage point for considering the oft-repeated conclusion from the deterrence literature that the certainty rather the severity of punishment is the more powerful deterrent. Consistent with the 'certainty principle,' the common feature of treatment conditions involving incarceration was a high certainty of imprisonment for failure to pay the fine. However, the fact that Weisburd and colleagues label the response the 'miracle of the cells' and not the 'miracle of certainty' is telling. Their choice of label is a reminder that certainty must result in a distasteful consequence, namely, incarceration in this experiment, in order for it to be a deterrent. The consequences need not be draconian, just sufficiently costly to deter proscribed behavior.

Helland and Tabarrok (2007) examine whether California's "Three Strikes and You're Out" law deters offending among individuals previously convicted of strike-eligible offenses. The future offending of individuals convicted of two previous

strike offenses was compared with that of individuals who had been convicted of only one strike offense but who, in addition, had been tried for a second strike offense but were ultimately convicted of a nonstrike offense. The study demonstrates that these two groups of individuals were comparable on many characteristics such as age, race, and time in prison. Even so, it finds that arrest rates were about 20% lower for the group with convictions for two strike offenses. The authors attribute this reduction to the greatly enhanced sentence that could have accompanied conviction for a third strike offense.

For most crimes, the certainty and severity of punishment increases markedly upon reaching the age of majority, when jurisdiction for criminal wrongdoing shifts from the juvenile to the adult court. In an extraordinarily careful analysis of individual-level crime histories from Florida, Lee and McCrary (2009) attempt to identify a decline in the risk of offending at age 18 years, the age of majority in Florida. However, they were unable to detect any significant change in crime risk.

In combination, these three studies nicely illustrate that the deterrent effect of the threat of punishment is context specific and that debates about whether deterrence works or not are ill posed. Instead, the discussion should be in terms of whether the specific sanction deters or not and if it does, whether the benefits of crime reduction are sufficient to justify the costs of imposing the sanction. To illustrate, while Helland and Tabarrok (2007) conclude that the third-strike effect in California is a deterrent, they also conclude, based on a cost-benefit analysis, that the crime-saving benefits are likely far smaller than the increased costs of incarceration. The Helland and Tabarrok study is an exemplar of the approach that should be taken in evaluating different sanctioning regimes.

The Deterrent Effect of Police

The police may prevent crime through many possible mechanisms. Apprehension of active offenders is a necessary first step for their conviction and punishment. If the sanction involves imprisonment, crime may be prevented by the incapacitation of the apprehended offender. The apprehension of active offenders may also deter would-be criminals by increasing their perception of the risk of apprehension and thereby the certainty of punishment. Many police tactics such as rapid response to calls for service at crime scenes or post-crime investigation are intended not only to capture the offender but also to deter others by projecting a tangible threat of apprehension. Police may, however, deter without actually apprehending criminals because their very presence projects a threat of apprehension if a crime were to be committed. Indeed, some of the most compelling evidence of deterrence involve instances where there is complete or near-complete collapse of police presence. In September 1944, German soldiers occupying Denmark arrested the entire Danish police force. According to an account by Andenaes (1974), crime rates rose immediately but not uniformly. The frequency of street crimes like robbery, whose control depends heavily upon visible police presence, rose sharply. By contrast, crimes like fraud were less affected.

The Andenaes anecdote illustrates two important points. First, sanction threats (or the absence thereof) may not uniformly affect all types of crime and more generally all types of people. Second, it draws attention to the difference between absolute and marginal deterrence. Absolute deterrence refers to the difference in the crime rate between the status quo level of sanction threat and a complete (or near) absence of sanction threat. The Andenaes anecdote is a compelling demonstration that the absolute deterrent effect is large. However, from a policy perspective, the important question is whether, on the margin, crime deterrence can be affected by incrementally manipulating sanction threats.

Research on the marginal deterrent effect of police has evolved in two distinct literature. One has focused on the deterrent effect of the aggregate police presence measured, for example, by the relationship between police per capita and crime rates. The other has focused on the crime prevention effectiveness of different strategies for deploying police. The authors review these two literature separately.

Aggregate Police Presence and Crime

Studies of police hiring and crime rates have been plagued by a number of impediments to causal inference. Among these are cross-jurisdictional differences in the recording of crime, feedback effects from crime rates to police hiring, the confounding of deterrence with incapacitation, and aggregation of police manpower effects across heterogeneous units, among others. Yet the challenge that has received the most attention in empirical applications is the simultaneity problem referred to in the previous section – in the present case, the feedback from crime rates to police hiring.

The two studies of police manpower by Marvell and Moody (1996) and Levitt (1997) are notable for their different identification strategies. The Marvell and Moody (1996) study is based on an analysis of two panel data sets, one composed of 49 states for the years 1968–93 and the other of 56 large cities for the years 1971–92. In order to overcome the problem of a bidirectional relationship between police manpower and the crime rate, they examine the effect of police manpower in the prior year on the crime rate in the current year. The strongest evidence for an impact of police hiring on total crime rates comes from the city-level analysis, with an estimated elasticity of -0.3, meaning that 10% growth in police manpower produces a 3% decline in the crime rate the following year, representing a modestly large effect.

However, regression analyses of this type do not generally provide a valid basis for making causal claims. But other forms of analysis can provide such a basis. One is an approach that exploits pseudorandom variation in policies that are only correlated with the crime rate through their effects on police manpower, in what is known as an instrumental variables (IVs) regression. Levitt (1997) performs this type of analysis from a panel of 59 large cities for the years 1970–92. Reasoning that political incumbents have incentives to devote resources to increasing the size of the police force in anticipation of upcoming elections, he uses election cycles to help untangle the cause–effect relationship between crime rates and police manpower. Levitt's model produces a very large elasticity of about -1.0 for the violent crime rate and a more modest but still meaningful elasticity of -0.3 for the property

crime rate. Following Levitt's use of the electoral cycle as an instrument for the number of sworn police officers, other studies have employed alternative IVs and reported comparable elasticities.

In recent years, a number of more targeted tests of the police–crime relationship have appeared. These studies investigate the impact on the crime rate of reductions in police presence and productivity as a result of massive budget cuts or lawsuits following racial profiling scandals. Each of these studies concludes that increases (decreases) in police presence and activity substantially decrease (increase) crime. By the way of example, Shi (2009) studies the fallout from an incident in Cincinnati in which a white police officer shot and killed an unarmed African-American suspect. The incident was followed by 3 days of rioting, heavy media attention, the filing of a class action lawsuit, a federal civil rights investigation, and the indictment of the officer in question. These events created an unofficial incentive for officers from the Cincinnati Police Department to curtail their use of arrest for misdemeanor crimes, especially in communities with higher proportional representation of African-Americans out of concern for allegations of racial profiling. Shi demonstrates measurable declines in police productivity in the aftermath of the riot and also documents a substantial increase in criminal activity. The estimated elasticities of crime to policing based on her approach were −0.5 for violent crime and −0.3 for property crime, both of which have policy significance.

The ongoing threat of terrorism has also provided a number of unique opportunities to study the impact of police resource allocation in cities around the world. The study by Klick and Tabarrok (2005) examines the effect on crime of the color-coded alert system devised by the US Department of Homeland Security (in the aftermath of the 11 September 2001, terrorist attack) to denote the terrorism threat level. Its purpose was to signal federal, state, and local law enforcement agencies to occasions when it might be prudent to divert resources to sensitive locations. Klick and Tabarrok (2005) use daily police reports of crime for the period of March 2002–July 2003, during which time the terrorism alert level rose from 'elevated' (yellow) to 'high' (orange) and back down to 'elevated' on four occasions. During high alerts, anecdotal evidence suggested that police presence increased by 50%. Their estimate of the elasticity of total crime to changes in police presence as the alert level rose and fell was −0.3.

To summarize, aggregate studies of police presence conducted since the mid-1990s consistently find that putting more police officers on the street – either by hiring new officers or by allocating existing officers in ways that put them on the street in larger numbers or for longer periods of time – has a substantial deterrent effect on serious crime. There is also consistency with respect to the size of the effect. Most estimates reveal that a 10% increase in police presence yields a reduction in total crime in the neighborhood of 3%, although studies that consider violent crime tend to find reductions ranging from 5 to 10%. Yet these police manpower studies speak only to the number and allocation of police officers and not to what police officers actually do on the street beyond making arrests. The next section proceeds from here by reviewing recent evaluations of deployment strategies used by police departments in order to control crime.

Police Deployment and Crime

Much research has examined the crime prevention effectiveness of alternative strategies for deploying police resources. This research has largely been conducted by criminologists and sociologists. Among this group of researchers, the preferred research designs are quasi-experiments involving before-and-after studies of the effect of targeted interventions as well as true randomized experiments, which are more difficult to implement and thus rarer, but yield the most internally valid results. The discussion that follows draws heavily upon two excellent reviews of this research by Weisburd and Eck (2004) and Braga (2008). As a preface to this summary, we draw the theoretical link between police deployment and the certainty and severity of punishment. For the most part, deployment strategies affect the certainty of punishment through its impact on the probability of apprehension. There are, however, notable examples where severity may also be affected.

One way to increase apprehension risk is to mobilize police in a fashion that increases the probability that an offender is arrested after committing a crime. Strong evidence of a deterrent as opposed to an incapacitation effect resulting from the apprehension of criminals is limited. Studies of the effect of rapid response to calls for service (Spelman and Brown, 1981) find no evidence of a crime prevention effect, but this may be because most calls for service occur well after the crime event, with the result that the perpetrator has fled the scene. Thus, it is doubtful that rapid response materially affects apprehension risk. Similarly, because most arrests result from the presence of witnesses or physical evidence, improved investigations are not likely to yield material deterrent effects because, again, apprehension risk is not likely to be affected. A series of randomized experiments were conducted to test the deterrent effect of mandatory arrest for domestic violence. The initial experiment conducted in Minneapolis by Sherman and Berk (1984) found that mandatory arrest was effective in reducing domestic violence reoffending. However, findings from follow-up replication studies (as part of the so-called Spouse Assault Replication Program) were inconsistent.

The second source of deterrence from police activities involves averting crime before it occurs, that is, crime prevention. In this circumstance, there is no apprehension because there was no offense. In the authors' view, this is the primary source of deterrence from the presence of police – the proverbial 'cop on the corner.' If an occupied police car is parked outside a liquor store, a would-be robber of the store will likely be deterred because apprehension is all but certain. Thus, measures of apprehension risk based only on arrest rates and reported crimes are seriously incomplete because such measures do not capture the criminal opportunities that were not acted upon by potential offenders because the risk was deemed too high. Consequently, there is reason to believe that deterrent effects of police presence are actually larger than what are commonly reported, because of the challenge posed by the measurement of behavior which never occurs.

Two examples of police deployment strategies that have been shown to be effective in averting crime are 'hot spots'

policing and 'problem-oriented' policing. A much broader review of these practices is provided in a recent National Academy of Sciences report (Committee to Review Research on Police Policy and Practices, 2004). Weisburd and Eck (2004) propose a two-dimensional taxonomy of policing strategies. One dimension is 'level of focus' and the other is 'diversity of focus.' Level of focus represents the degree to which police activities are targeted. Targeting can occur in variety of ways, but Weisburd and Eck give special attention to policing strategies that target police resources in small geographic areas (e.g., blocks or specific addresses) that have very high levels of criminal activity, so-called crime hot spots. Just as in the liquor store example, the rationale for concentrating police in crime hot spots is to create a prohibitively high risk of apprehension and thereby to eliminate the opportunity to commit crime at the hot spot in the first place.

Braga's (2008) informative review of hot spots policing summarizes the findings from nine experimental or quasi-experimental evaluations. The studies were conducted in five large US cities and one suburb in Australia. Crime-incident reports and citizen calls for service were used to evaluate impacts in and around the geographic area of the crime hot spot. The targets of the police actions varied. Some hot spots were generally high-crime locations, whereas others were characterized by specific crime problems like drug trafficking. All but two of the studies found evidence of significant reductions in crime. Further, while not all of the studies examined crime displacement, among those studies that did, no evidence was found of material displacement to immediately surrounding locations. On the contrary, some studies found evidence of crime reductions, not increases, in the surrounding locations – a 'diffusion of crime-control benefits' to non-targeted locales.

The second dimension of the Weisburd and Eck taxonomy is diversity of approaches. This dimension concerns the variety of approaches that police use to impact public safety. Low diversity is associated with reliance on time-honored law enforcement strategies for affecting the threat of apprehension, for example, by dramatically increasing police presence. High diversity involves expanding beyond conventional practice to prevent crime. One example of a high-diversity approach is problem-oriented policing. Problem-oriented policy comes in so many different forms that it is regrettably hard to define.

One of the most visible examples of problem-oriented policing is Boston's Operation Cease Fire (Kennedy et al., 2001). The objective of the collaborative operation was to prevent intergang gun violence using two deterrence-based strategies. One was to target enforcement against weapons traffickers who were supplying weapons to Boston's violent youth gangs. The second involved a more innovative use of deterrence. The youth gangs themselves were assembled (and reassembled) to send the message that the response to any instance of serious violence would be 'pulling every lever' legally available to punish gang members collectively. This included a salient severity-related dimension – vigorous prosecution for unrelated, nonviolent crime such as drug dealing. Thus, the aim of Operation Cease Fire was to deter violent crime by increasing the certainty and severity of punishment but only in targeted circumstances, namely, if the gang members were perpetrators of a violent crime. Just as important, Operation Cease Fire illustrates the potential for combining elements of both certainty and severity enhancement to generate a targeted deterrent effect. Further evaluations of the efficacy of this and other problem-solving strategies should be a high priority.

Conclusions

This article has reviewed the evidence on the general deterrent effect of the use of imprisonment as a sanction for criminal behavior, as well as the size of police departments and selective policing strategies. Evidence of substantial deterrent effects is considerable. Therefore, a well-balanced portfolio of strategies and programs to prevent crime must necessarily include deterrence-based policies. That being said, policy makers should be sensitive to the possibility that not all deterrence policies will be effective in reducing crime or, if effective, that the crime-reduction benefits may fall short of the social and economic costs of the sanction. A 'one-size-fits-all' crime policy is hard to justify.

Future research on the utility of prisons and police for crime control will be most useful for policy evaluation if it moves closer to a medical model. Medical research is not organized around the theme of whether medical care cures diseases, the analog to the question of whether criminal justice agencies prevent crime. Instead, medical researchers address far more specific questions. Is a specific drug or procedure effective in treating a specific disease? Does the drug or procedure have adverse side effects for certain types of people? Furthermore, most such research is comparative – is the specific drug or procedure more effective than the status quo alternative? The analogous questions for deterrence research are whether and in what circumstances are the use of police and prisons the most effective.

Abstract

Karl W Deutsch remains in the history of political science as a leading figure in three domains: comparative politics, quantitative analysis, and international relations. He had a great capacity to interpret statistical data with an intimate knowledge of the historical and social contexts. Several concepts designed or developed by him, like social communication, rate of political mobilization, or spread of national consciousness, belong today the common patrimony of social sciences. In the field of international relations, he has emphasized the importance of transnational trade for political integration. Deutsch is author, co-author, editor, or co-editor of 16 books and more than 200 articles in academic journals. His most important books are *Nationalism and Social Communication*, *Political Community at the International Level*, and *The Nerves of Governments*. As an interdisciplinary scholar, Deutsch has co-edited a book on *Advances in the Social Sciences, 1900–80*.

Karl Wolfgang Deutsch belongs to the cohort of the 'brain drain' which, by emigrating in the 1930s from Europe, contributed to the development of the social sciences in the United States. Born in Prague on 21 July 1912, Deutsch escaped from the imprisoned continent in 1939, after having received a law degree from Charles University. Son of the first woman parliamentarian in Czechoslovakia, he moved from one privileged social stratum to another, debarking with a fellowship at Harvard University. He worked for the Office of Strategic Studies during World War II, began teaching at MIT in 1945, then at Yale University in 1957 and, from there, taught at Harvard University until retiring in 1985. At that time, he was appointed as one of the directors of the Wissenschaftzentrum in Berlin. As is often the case with those who learn a new language after puberty, Karl Deutsch kept his distinctive German accent. He died at the age of 80 in Cambridge, MA, on 1 November 1992.

Karl Deutsch's contributions to the advancement of social sciences can be summed up in five domains:

1. Building empirically grounded concepts and theories, such as nation-building, social mobilization, national and international integration, center–periphery, distribution of power, and understanding macrosocial processes. His definition of integration of a society is still in use in the literature: the capacity to receive and transmit information on wide ranges of different sectors with little delay. One of his writings appears retrospectively as predictive: "Cracks in the monolith, possibilities and patterns of disintegration in totalitarian systems" (Deutsch, 1954).
2. Pioneering, cross-national research. Deutsch remains a leading figure of the first post-War generation of comparativists. In the late 1950s and 1960s, he did comparative research, using aggregate data at a time when other great comparativists, such as Gabriel Almond and Sidney Verba, preferred the survey method for comparing countries.
3. Quantitative methodology. Karl Deutsch advanced the introduction of statistical analysis in political science. Such a vocation could be explained by the fact that, as the son of an optician, early in life, Deutsch considered the possibility of becoming one himself, and consequently studied mathematics. He did quantitative analysis on the size of government, growth of governments, foreign trade as a percentage of GDP, global modeling, two-way channels of communication between élites and mass. Deutsch was in the forefront of the so-called 'data movement.' His contribution to *Quantitative Ecological Analysis in the Social Sciences* (Deutsch, 1969) was considered as a research agenda.
4. Work on communication theory, particularly cybernetics. He developed Wiener and Neumann's research, focusing on politics and society. The subtitle of *The Nerves of Government*, 'Political Communication and Control,' (Deutsch, 1963) paraphrases Wiener's definition of cybernetics: 'Control and Communication in the Animal and Machine.'
5. Bridges between disciplines, by importing in political science concepts and theories from various disciplines (anthropology, social psychology, economics, and biology). *Nationalism and Social Communication* (Deutsch, 1953) is an eminently interdisciplinary work, where Deutsch's intimate knowledge of European history and geography appears in all chapters. Deutsch was a leading contributor to *Advances in the Social Sciences* 1900–80 (Deutsch et al., 1986).

Retrospectively, it can be said that Deutsch's most eminent book is his first, *Nationalism and Social Communication*: *An Inquiry into the Foundation of Nationality* (1953). This is his most cited work, and has been so since its publication. The subject of this book is related to his personal experience. Born to a Sudeten German family in the Austro-Hungarian empire, a multinational state, "Deutsch put his emotional and intellectual energy into scholarship focused upon nationalism and formation of large-scale political communities" (Merritt and Russett, 1981: 6). As a teenager, Deutsch witnessed the collapse of three empires and the emergence of many new independent nation-states in Eastern Europe and the Balkans.

The success of this book can be explained by Deutsch's capacity to interpret statistical data with an intimate knowledge of the historical and social contexts. There are social scientists who write about countries they have only read about in books and who, in spite of their statistical virtuosity, too often offer superficial explanations. They should contemplate the following: "We will always need the clinician who knows the problem from having seen many cases, who knows the

countries, the cultures, the areas where the problem takes place, and who knows the particular syndromes. It is by equipping the clinician with the work of the technicians, by having clinical judgement and technological and scientific evidence side by side, that we are likely to make the most progress" (Deutsch, 1980: 19).

In a survey of the most commonly cited political scientists, Deutsch's name ranked eighth between 1945 and 1960, fourth from 1960 to 1970, and tenth between 1970 and 1976. After 1980 his name still appears on the list of the three dozen most-cited political scientists. Between 1970 and 1979, his name was cited 1870 times. Between 1996 and 1999 he has been cited 60–90 times per year. Most of them concern the following three books: *Political Community at the International Level* (Deutsch, 1954), *Nationalism and Social Communication* (Deutsch, 1953), and *The Nerves of Government* (Deutsch, 1963).

It is interesting to note that Deutsch's two most successful books were conceived and written simultaneously, and were published only one year apart, in 1953 and 1954. Undoubtedly the fundamental ideas for these two works were already present in his mind when he escaped from the totalitarian regime. *The Nerves of Government* does not appear to be Deutsch's most popular book. It has been cited less frequently than the other two and, when it has been cited, the citations were in many cases perfunctory, the content not being commented upon. This book was published in 1963, at a time when Deutsch had already been at the front of the stage. Such perfunctory practice has been described by Robert Merton in his *Sociology of Science*.

The high 'mortality' rate of articles in political science, particularly in the field of international relations, is a well-known phenomenon. In several other disciplines, the life expectancy rate of articles is longer. Karl Deutsch published as author, co-author, editor, and co-editor a total of 16 books. In addition, between 1943 and 1980, he published 240 articles in academic journals and chapters in collective works, approximately half of them in collaboration with other scholars. According to the SSCI, which covers as sources only journals, excluding books, some of these 240 contributions were still being cited during the 1990–95 quinquennium. The content of some of Deutsch's articles has become chapters of his books, particularly in *The Nerves of Government*. Other articles, among the best *Towards an Inventory of Basic Trends and Patterns in Comparative and International Politics* (1960) and *Social Mobilization and Political Development* (1961), have become standard information and common knowledge, and, consequently, do not need to be cited. What had been previously innovative has been superseded by more recent studies based on more precise data, analyzed with more refined methods. When writing about microbes, Pasteur need not be cited. When using social indicators, Karl Deutsch, Gabriel Almond, and Daniel Lerner no longer need to be cited. The concept of social mobilization already belongs to the common patrimony of the social sciences.

In the late 1960s and 1970s, Yale's Department of Political Science was one of the most attractive for graduate students, many of whom converged in Deutsch's seminars. One of these seminars inspired the conception of an important book entitled *World Handbook of Political and Social Indicators*, which users of quantitative data had named 'the Yale bible,' by Bruce M. Russett in collaboration with H. R. Alker, K. Deutsch, and H. Lasswell (Russett et al., 1964).

The following are among Deutsch's intellectual progeny: Hayward Alker, Jorge Dominguez, William Foltz, Michael Hudson, Peter Katzenstein, Manfred Kochen, Arendt Lijphart, Richard Merritt, Donald Puchala, Bruce Russett, Charles Taylor, these and others recognized as outstanding political scientists. They honored their mentor in a collective book *From National Development to Global Community*, edited by Richard L. Merritt and Bruce M. Russett (1981).

Stein Rokkan's tribute to Deutsch's intellectual leadership deserves to be cited at length: "Karl Deutsch taught my generation of social scientists to develop models and to test them against the data of history. My own early research was heavily influenced by Deutsch's ideas. My later work on dimensions of state formation and nation-building was directly inspired by Deutsch's path-breaking study *Nationalism and Social Communication*; he taught me to look out for the decisive characteristics of center-building networks and to study the functions of the printed media" (Rokkan, 1981: 70).

Deutsch was an interdisciplinary scholar, comfortable in many fields. In his latter days he became interested in 'the conditions favoring major advances in the social sciences.' In 1986, he co-edited a volume focusing on this subject in collaboration with Andrew Markovits and John Platt (Deutsch et al. 1986).

Those who encountered Deutsch were impressed by his encyclopedic erudition. In his book *Nationalism and Social Communication* (Deutsch, 1953) some 2000 authors are mentioned. His historical knowledge appears in a particular light in an article published in 1945 on 'Anti-semitic ideas in the Middle Ages,' based on the reading of very old literature (Deutsch, 1945). This article merits to be included in any modern anthology of historical sociology.

Soon after the publication of *The Limits to Growth* by the Club of Rome in 1972, a new trend appeared in political science, imitating economists, demographers, and ecologists. Karl Deutsch had alerted the specialists: "Computers can assist thought, but not replace it. Mathematical thought produced new ideas and techniques, such as game theory and coalition theory, scaling, latent structure analysis, matrix analysis and a succession of increasingly sophisticated models of social and political structures and processes ... Some of us have tried to deal with this by over-specialization, risking to fall into the old trap of learning more and more about less and less" (Deutsch, 1978). Nevertheless, in the 1980s, he was seduced by the siren of 'world modeling.' Under his directorship at the Wissenschaftzentrum in Berlin, modeling became a priority. The virtue of Deutsch's effort in Berlin was to combine mathematical modeling and solid empirical referent. Abstract mathematical modeling has attracted the attention of a limited number of political scientists outside the circle of the builders of reductionist models.

World trade was one of Deutsch's favored topics, which he discussed in several writings. He measured the ratio of foreign trade to national income for almost half a century. He presented an impressive amount of statistical data demonstrating a decline in international trade between 1913 and 1957 (Deutsch and Eckstein, 1961). But this period was marked by World War I, the Great Depression, protectionism, and autarchy practiced by several great powers in the 1930s, World War II, and the post-War reconstruction of the

devastated European countries and Japan. In the 1950s, only 6% of the American GNP depended on foreign trade. Deutsch did not explicitly predict a continuing decline of international transaction. More recent developments do not invalidate Deutsch's historical observation.

One of Deutsch's main ideas was the importance of intertwining economies for political integration. This thesis is still validated: half of France's foreign trade takes place with Germany, and reciprocally. Economic integration has preceded political integration of the European Union, even for Britain.

Since the publication of *Nationalism and Social Communication*, the nations of Western Europe, with the exception of Greece and Ireland, have experienced a rapid decline of nationalist tendencies, reversing a historical trend (Dogan, 1993), at a moment when, in contrast, many developing countries in Asia, the Middle East, and Africa have been mobilized by movements of national independence, developing an exacerbated ethnic nationalism. The concepts designed by Deutsch and other scholars – social communication, rapidity of assimilation, rate of mobilization, spread of national consciousness, population clusters, linguistic cleavages, center–periphery – have been transplanted from the continent to which they were first applied to many new nation-states, where Deutsch's theories are more relevant.

Karl Deutsch's professional career was one of exceptional brilliance. He was elected President of the American Political Science Association in 1969 and of the International Political Science Association (IPSA) in 1976, playing an important role in the development of the research committees within IPSA. In collaboration with Richard Merritt, as program director, he organized the IPSA World Congress in Moscow in 1979, building a bridge between East and West for political scientists. A member of the American Academy of Sciences, he lectured in many European universities. Deutsch received honorary doctorates from seven American and European universities and the Commander's Cross Order of Merit from the German Federal Republic.

Abstract

The past three decades have witnessed major changes in the economic and social fabric of developing and emerging economies, bringing new opportunities but also challenges. Addressing the latter requires a complex set of factors that shape the investment climate and promote sustainable growth and job creation in the formal sector. Labor market, social policy, and institutions can not only facilitate the required reallocation of workers toward more rewarding and productive jobs but also provide adequate support to those affected by these changes. This requires improving the institutional fit of labor institutions with the reality of the different countries and devoting adequate resources to effective social protection programs. Strong economic development is key for more but also productive and rewarding jobs, and better jobs are key to ensure the benefits of growth are widespread and conducive to improvements in the well-being of the population.

Introduction

Job creation is often at the top of the development agenda, for policy makers as well as for social partners and civil society. This is because labor is more than a factor of production; it is an essential element of any development process, of well-being and social cohesion. Labor is the main asset of people; the type of work people hold is one of the most powerful determinants of well-being, as, over their lifetime, most people spend a substantial part of their time at work. Moreover, it is an essential factor of production for firms of all types and sizes. Even in high-tech manufacturing firms, workers bring new skills and competencies to enhance the organization of production or to improve the quality and variety of products. The way in which employers' demand for labor and households' supply of it interact is crucial in determining the conditions in which firms find the proper incentives for engaging in growth enhancing activities and workers participate in, and benefit from, these activities.

Labor markets have been profoundly affected by global developments in the past decades. The transition of many developing countries and former centrally planned economies to market-based systems and the greater integration of countries in the global economy have changed the rules of the game within which businesses, governments, and workers interact. The opening of domestic markets has exposed previously protected firms to greater competition but also to new, more productive technologies. The scale of production has often changed, from large oligopolies protected by trade barriers, to smaller, but often more technologically advanced, production units. Overall, firms are facing greater pressure to innovate in order to survive and expand.

These changes have created new economic opportunities, but also exposed firms and workers to new challenges. Greater integration in world markets have enhanced opportunities for entrepreneurs to launch new activities and for existing firms to expand, both contributing to a faster job creation in expanding sectors. But technological advances and expanding international interactions have also changed comparative advantages of individual countries and threatened firms and jobs in declining sectors. More generally, pressure has increased to make work arrangements more adaptable to enable firms to respond to changing economic and technological conditions. In many developing and emerging economies, labor market policy and social security systems are often underdeveloped, and many workers are increasingly exposed to the volatility of a more competitive, open but also more risky economic environment.

The nature of jobs is varied. As recently indicated (World Bank, World Development Report 2013), of the three billion people at work, more than half are employed and receive regular wages or salaries; the rest work in farming and small household enterprises, or in seasonal or casual day labor. And while there are about 210 million people unemployed worldwide, two billion working-age adults, the majority women, are neither working nor looking for work, even if a number of them are eager to have a job. Understanding the nature of work relations and how they are evolving as part of the development process is crucial to design adequate policies and institutions that promote strong but also sustainable and job-rich economic growth.

Fostering Job Creation and the Efficient Utilization of Labor

Recent Developments

Efficient utilization of labor is essential for sustainable long-term economic growth. This entails high levels of employment, enhancement of human capital, and labor mobility. A simple decomposition of the sources of economic growth over the past decades suggests that the combined effect of greater utilization of labor and enhancement in human capital have generally made a significant contribution to improvements in output per capita. Many countries that have seen improvements in their growth performance over the past decades have also seen improvement in the quality of the workforce and in some cases an increase in the employment rate (the share of the total working age population involved in productive activities).

The views expressed herein are those of the authors and should not be attributed to the their organisations of affiliation.

Even more importantly, efficient utilization of labor is critical for poverty reduction. Household living standards, especially amongst the poor, are closely tied to their income from work, and a labor market that leads to high labor utilization, especially in formal activities, is a key vehicle to reduce poverty and exclusion. Economic development has led to significant reductions in poverty. For example, an estimated 447 million workers in emerging G20 economies were extremely or moderately poor in 2013, a reduction by half since 1991 (World Bank, 2013). Yet, more remains to be done; working poverty and near poverty remain large and widespread challenges for these countries. Taking into account these near-poor workers, some 837 million workers, equal to just over half of the workforce in emerging G20 countries, were either poor or just above the poverty line in 2013 (Kapsos and Bourmpoula, 2013).

Some countries – especially in East and South Asia – have been successful in combining strong economic growth with a rising labor utilization and enhancement of human capital. However, many countries face weak labor market conditions, which have been compounded by the recent financial crisis. Poor labor market outcomes have been driven in many countries by private job creation not keeping pace with the increase in the working age population and/or the increase in female participation in the labor market. In a number of countries in the Middle East and North Africa, the state has been a leading and generous employer but as the fiscal space for continued expansion in the public sector is shrinking, 'queuing' for public sector jobs has become more prevalent, leading to informality, a devaluation of educational credentials, and forms of social exclusion and unrest in a number of them (see Nabli et al., 2008; Assaad, 2012). In the former Soviet block, after a period of practically full employment, unemployment rates reached two-digit levels in the early phases of the transition to a market economy. Many of those countries still face relatively high rates of joblessness and falling employment (see inter alia, Rutkowski and Scarpetta, 2005). In Latin America, many countries, including those that had sustained growth prior to the global financial crisis, have seen unemployment and inequality increase, even if recent reforms and effective transfers to the poor have contributed to reduce household income inequality (e.g., Brazil, Chile, and Mexico) (see Pagés, 2010; Pagés et al., 2009). While measured unemployment has remained relatively low in South Asia, the share of working poor is still around 40% on average in the region. Advanced economies have been hit by the global financial and economic crisis of 2008–09, which has led to a large increase in unemployment and underemployment in a number of economies, often concentrated on the most vulnerable groups, including the youth, the low skilled, and migrants (see OECD, *Employment Outlook*, 2013; see also OECD-ILO, 2014; OECD, 2010b).

These unsatisfactory outcomes are both due to poorly functioning labor markets, as well as failures of other markets to promote strong and sustainable, and thus job-rich, growth. High and persistent unemployment in some countries, a large informal sector or low participation in others partly reflect the inability of labor market to facilitate labor mobility and promote firms' investment, because of restrictions in wage or labor adjustments or low incentives for investment in human capital. At the same time, failures in other markets, by curbing firms' developments, also limit the process of job creation and wage improvements. Some deterioration in labor market conditions may also be a temporary side effect of structural reforms aimed at improving the investment climate. For example, macroeconomic reforms, trade liberalization, or large-scale privatization all require large reallocation of workers and changes in skills. Even in the best of all possible labor markets, such changes may lead to temporary increases in unemployment and loss of income, as workers need to change job, acquire new skills, and sometimes change location.

In practice, it is difficult to disentangle these different elements as labor markets interact closely with other markets and reforms impose pressure on all of them also affecting these interactions. Bearing these caveats in mind, the remainder of this section will shed some light on these linkages in turn.

How Adaptable Are Labor Markets in Developing Countries?

Different factors contribute to the adaptability of the labor market and thus its ability to contribute to promote investment, job creation, and growth. First, firms should be allowed to adjust wages and employment to changing demand conditions and to adopt new technologies. Second, market economies require a continuous reallocation of labor away from declining firms and industries toward expanding ones, and labor markets have a key role in facilitating this process and thus contributing to productivity gains and better prospects for workers (see, e.g., Bartelsman et al., 2013). Developing and emerging economies differ with respect to actual labor market adaptability, although lack of relevant information often makes it difficult to depict a comprehensive picture.

Evidence suggests a significant – and often growing – response of wages to changes in labor market conditions in some countries. At the same time, in many countries a substantial number of jobs are created and destroyed every year pointing to a continuous process of labor reallocation. In particular, structural reforms have sometimes changed the responsiveness of wages to labor market conditions. (For example, in Chile there was no evidence of the wage curve during the period of inward-led development (1957–73), but the curve emerged along with the opening of the economy and regulatory reforms (post 1974). See Berg and Contreras, 2002.) However, it should be stressed that the flexibility of real wages in many developing countries has often been achieved in the past by the lack of full indexation of nominal wages during periods of high inflation in downturns. In a low inflation environment and given the natural tendency for workers to resist nominal wage reductions, the ability of wages to accommodate demand fluctuations may be reduced. (For example, wage elasticity in Argentina in the 1980s – a period of high inflation – was about 10 times higher than wage elasticity in the 1990s – a period of lower inflation – and employment elasticity in the 1990s was twice as large as employment elasticity in the 1980s. See IADB, 2003.) In any event, wage adjustments cannot be the only factor to accommodate changes in labor demand, especially in countries undergoing major structural changes, where new firms replace obsolete ones, new sectors emerge, and new technologies have to be adopted to maintain competitiveness.

Most low- and middle-income countries have experienced significant shifts in employment, away from low-productive agricultural activities to manufacturing and, especially, new service activities (see World Bank, World Development Report

2013 for an up-to-date review). This secular trend away from agriculture and toward manufacturing and services hides significant differences in the ability to match labor demand and supply. In countries for which data are available, gross rates of job creation and destruction each range between 5 and 20%, adding up to a total job turnover of up to 40% (see Haltiwanger et al., 2014). A significant fraction of this job turnover (often 30–50%) is due to the entry and exit of firms, an important factor for output and productivity growth. (It should also be noted that in all countries, worker turnover is even larger than job turnover, because workers not only move directly from one job to another, but also between employment and unemployment and inactivity as a result of their own personal decisions. See OECD, *Employment Outlook*, 2012.)

This sizable process of creation and destruction of jobs in most countries does not necessarily mean that the reallocation of labor has been efficient. The latter depends on whether job flows lead to the allocation of workers to most productive use and thus are associated with productivity growth and wage increases.

In particular, job destruction may be inefficient if, for example, capital markets constrain the ability of firms to cope with negative shocks and retain valuable workers. Credit constraints are a severe problem for small firms in many developing countries and it is thus not surprising that these firms tend to have higher levels of job reallocation. (See Caballero et al. (2004) for a discussion of the ability of different firms to adapt to negative shocks.) Moreover, certain labor market policies may inflate job flows, without necessarily leading to better outcomes.

In addition, labor reallocation may go in the wrong direction, especially if dismissed workers cannot properly search for jobs because they cannot afford to remain without income. For example, in Latin American countries dismissed workers often go to the informal sector because the lack of unemployment benefits prevent them for properly searching for another (formal job) (see IADB, 2003; Pagés et al., 2009).

Moreover, a major consequence of labor reallocation is large flows of workers across regions. Traditional models have emphasized the role of rural–urban migration as a key engine of development (see Fields, 2004 for a review). But whether these large domestic flows of workers smooth labor market pressures and contribute to a better allocation of resources depend on the characteristics of those who migrate and on policies that may influence the decision at the individual or household levels. For example, large flows of often unskilled workers are likely to increase unemployment in receiving urban areas if labor demand does not respond quickly. Immigrants in urban areas may be low skilled compared to the urban labor force, but they are generally young with relatively better education than the local workforce. Hence, emigration may reduce the potential for rural development if remittances toward rural areas do not compensate for the loss of human capital.

International migration may also be considered as a factor in promoting efficient allocation of resources, but, at the same time, may deprive a country of its main human capital assets. Recent research also point to the benefits of emigration, in particular, through the potentials offered by remittances and the role that returning emigrants may play for local development. Remittances have become an important aspect of global development finance (see World Bank, Migration and Remittances Briefs (various issues)). They are often used to support family members and can stimulate domestic demand as well local investment. Many relatively high-skilled emigrants also return to their home countries and establish their own business. Several East Asian economies have benefited from the return of migrants to the home country.

The Policy Challenges of Promoting More and Better Jobs for Development

Although the idea that a well-functioning investment climate is essential to generate higher demand for labor and for enabling wages to rise is well accepted, some of the key reforms that are necessary to promote the investment climate are often perceived as harmful by workers. Evidence points to significant long-term benefits from a comprehensive reform of the investment climate, in terms of both access to better jobs and reduced unemployment and underemployment. Most of these reforms, however, imply major changes which have short-term costs, especially for workers in firms previously protected, for example, by trade barriers, state support or lack of competition, and for workers with low skills or in declining areas. Often, these costs are exacerbated by the fact that reforms are implemented in the aftermath of a major economic crisis when the choice of the reform package or its implementation occurs when the economy is already undergoing painful adjustments. (This is indeed the case of a number of reforms undertaken during the recent financial and economic crisis in a number of advanced economies – especially in Southern Europe. For a review, see OECD, *Employment Outlook*, 2014.)

Adequately designed reforms of the investment climate – be it via enhancements in product market competition, greater transparency, or more secure property rights – have all the potentials for improving workers' welfare over time. Successful reforms are expected to bring about higher wages and better working conditions, as well as higher employment and lower levels of unemployment and informality in the long run (see Bourguignon and Goh, 2003; De Ferranti et al., 2000; Gill et al., 2002). Empirical studies that have linked different structural reforms to labor market outcomes seem to confirm these points, although they also strongly underline the importance of a comprehensive and well tailored approach that is consistent with underlying economic conditions in each country. For example, countries which have opened their economies to greater foreign trade have enjoyed higher economic growth and higher wages compared to those which have persisted in the inward-oriented strategy (see amongst others; Dollar and Kraay, 2001; Rodrik, 1997; Rama, 2003).

Trade liberalization is an important reform to improve the competitiveness of a country, which can lead to better labor market outcomes. Greater exposure to foreign competition strengthens incentives for firms to invest in new technologies and in enhancement of the human capital and skills of their workforce. Moreover, within each individual country, sectors exposed to stronger competitive pressure tend to have higher labor productivity and pay higher wages than those concentrated on the internal markets, even for workers of similar characteristics. Similarly, there is evidence that foreign

owned firms in developing countries tend to pay premium wages and provide better working conditions, which reflect their better productivity performance associated with foreign ownership and especially easier access to foreign markets and technologies (see Brown et al., 2003).

Despite often being singled out as the main cause behind greater economic volatility and greater income and job security for workers, trade liberalization does not appear to increase wage disparity in the long run (see, e.g., OECD, 2011). Open economies tend to be more exposed to fluctuations in global demand and to changes in relative prices. But in the long run, there is little evidence that trade liberalization has led per se to an increase in the year-to-year fluctuations in earnings, nor are wages more volatile in sectors more exposed to foreign competition – a result which applies to a wide range of countries in Asia and Latin America (Bourguignon and Goh, 2003; De Ferranti et al., 2000; Pagés, 2010). At the same time, there is no strong evidence that, by fostering competition amongst domestic firms, countries have increased the elasticity of labor demand with respect to wages: no such effect was found in India, Turkey, and a sample of Latin American countries (Epifani, 2003; Fajnzylber and Maloney, 2000).

It must be recognized that many of the reforms aimed at improving the investment climate have short-term and long-term impacts on the structure of the labor market. They may well imply changes in the nature of jobs, with a decline in stable jobs in sectors sheltered from competition and lower job tenure. They are often associated with short-term adjustment costs – in terms of employment losses and major changes in relative wages. These costs can be large and protracted if the reallocation of resources associated with most structural reforms is sluggish, because relative prices do not adjust, because labor adjustment costs are high, or because old jobs are destroyed before new jobs are created. For example, empirical studies suggest that wages may well decline in the wake of trade liberalization, before they begin to rise again, usually at a higher pace (see, e.g., Rama, 2003). Moreover, structural reforms prompt large reallocation of resources, including labor. Job destruction and job creation might not be fully synchronized thereby giving rise to some temporary increase in unemployment, or the expansion of informal activities especially in countries where workers cannot afford to remain without a job.

The adjustment costs associated with most structural reforms tend to be borne by the most vulnerable groups in the labor market. These groups include individuals with low levels of education, or with a specialization which is no longer demanded in the market, and those with little work experience or in geographical locations dominated by backward activities. In developing and industrial countries alike, low-skilled workers, youth, and often prime-age women with little work experience tend to face a high incidence of unemployment, informality, or low pay. (See OECD, *Employment Outlook*, 2013, for a review of the impact of the global financial crisis of 2008–09 on different sociodemographic groups.) These unfavorable conditions for vulnerable groups tend to deteriorate even further during the initial phases of large-scale structural reforms. Workers with little experience tend to be the first to be dismissed in case of downsizing and the low skilled face the greatest difficulties if they lose their jobs. These difficulties can be particularly severe if the adjustment process follows a crisis that has plunged the economy into a recession or if the renewal of growth takes longer than originally expected. For all these reasons it is vital to adopt a comprehensive reform strategy that includes adequate labor market and social protection policies to support workers and households affected by the structural transformations.

Labor Market Institutions: Governing Worker–Firm Relations

Policy makers intervene in the worker–firm relations on two main fronts. They set regulations for working conditions and the labor contract between workers and employers, and they fix wage floors and set the legal framework in which social partners operate. These interventions are theoretically justified by the (perceived or effective) inability of laissez-faire conditions to deliver efficient and equitable outcomes. Efficiency arguments stress information problems and a need to promote matching between labor demand and supply. There are also equity arguments if there is unequal bargaining power between employers and workers, potential discrimination against vulnerable groups, or incomplete or imperfect insurance of workers against risks. The policy priorities for improving labor market outcomes vary greatly across countries, depending on their level of development, institutional settings, and social preferences. (See the World Development Report 2013 of the World Bank for a review of the typology of job challenges.)

Intervening in the Wage-Setting Process

The success of fostering opportunities for firms to invest productively largely depends on their ability to remunerate factors of production, including labor, according to their productivity and to adjust input prices to accommodate changes in demand. Properly compensating workers also fosters their effort in the production process and strengthens their incentives to invest in human capital. Governments intervene in the wage-setting process by establishing rules for wage bargaining and for industrial relations.

Setting Wage Floors

The main objective of setting wage floors is to promote decent jobs and reduce poverty among workers. Wage floors also tend to control market power that companies may have over individual workers who lack information, bargaining power, or the ability to seek better-paid jobs. This is particularly the case in monocultural areas, where a single company may account for the bulk of labor demand. The effectiveness of wage floors in many low- and middle-income countries is, however, questionable. Minimum wages tend to be fairly high compared with market wages in a number of these countries, and any further increase would shift the entire wage distribution upward. This concentrates the disemployment effects among those they intended to support – young, low skilled, and female workers. When enforcement is weak, a hike in the minimum wage stimulates more underreporting of wages or further incentives for firms and jobs to remain in the informal economy. However, a number of emerging economies have recently raised the minimum wage relative to the average wage (often from very low levels) as a way to fight working poverty and boost

household income, without sizeable disemployment effects (see OECD-ILO-WBG 2014 – *G20 labour markets: outlook, key challenges and policy responses*).

Setting Workplace Regulations

Promoting better health and safety conditions in firms, regulating working time, and encouraging paid annual leave have been major achievements in all societies, and well-designed regulations can help to achieve this goal. The beneficial impact of such regulations may, however, be limited if they, or other features of labor regulation, have the effect of keeping firms and workers in the informal economy, where workers usually lack any statutory protection. Stronger enforcement can help in some cases. However, when regulations are out of step with local realities, there will be trade-offs between providing a high level of protection to workers in regulated employment and reaching a broader group of workers.

Balancing Employment Stability with Firms' Need to Adjust the Workforce

Probably the most controversial government intervention in the labor market is setting rules for hiring and firing workers. By affecting the cost of workforce reorganization, employment protection legislation strongly influences the cost of doing business, but especially the incentives and opportunities for firms to exploit new technologies and expand. The protection offered to regular workers and the conditions for temporary employment vary considerably across and within regions. Countries in Latin America, Eastern Europe, and Central Asia tend to offer the most employment protection for regular workers. By contrast, 'common law' industrial countries and East Asian economies have the lowest statutory protection. Beyond ensuring full respect for the core labor standards, setting adequate regulations on hiring and firing procedures can benefit both workers and firms. For example, by reinforcing job security, they can enhance productivity, as workers will be more willing to cooperate with employers (see Martin and Scarpetta, 2012 for a review of the literature, as well as Addison and Teixeira, 2001; Heckman and Pagés, 2004; Betcherman, 2012). To the extent that job protection leads to long-lasting work relationships, it may encourage employers to provide training. A better skilled workforce may also increase internal flexibility and thus lead to a better functioning of production activity. Job protection may also be a way to internalize the social costs of dismissals by moving the social burden of reallocating a worker to another job closer to the firm's profitability criteria.

Given the high level of protection granted to workers in the formal sector in many developing countries, it is not surprising that managers often consider such regulations as an obstacle for the expansion of their firm. In fact, overly stringent regulations – those at odds with the international experience and with the stage of development of the economy – affect different aspects of firms' performance, including spending on innovation, the entry of new firms, their average size, and the incidence of informality.

Strict regulations in industrial countries, where enforcement is high, tend to promote job stability for prime-age males, but tend to reduce job opportunities and lengthen unemployment spells for youths, women lacking work experience, and those with low skills. Firms may become reluctant to hire new workers from these groups for fear of incurring expensive dismissal costs in the future.

When enforcement is weak, as it is in many low- and middle-income countries, stringent regulations do not reduce the size of labor reallocation, but they do change its nature and reduce its effectiveness. Women, youths, and the unskilled – facing greater difficulties in obtaining a job in the formal sector – are more frequently unemployed or engaged in informal activities.

Active Labor Market Policies: Promoting Workers' Adaptability and Mobility

Many countries face the challenge to equip their future labor force with skills and competencies that are relevant for the labor market. This involves important reforms in the education and training systems to improve the coverage and quality of education and enhance learning outcomes. Such reforms should be started now and will bear fruits for future generations of workers.

At the same time, there are a number of measures that governments can use to improve the ability and willingness of current workers to move to more productive and rewarding jobs. Such policies include supporting job intermediation and training. The effectiveness of these programs has been challenged especially in countries with limited capacity, but when properly targeted they can be a complementary strategy to skill enhancements and income support.

Job search assistance is aimed at promoting transparency and information in the labor market so as to facilitate job matching. In this respect, it offers a service to both employers who have otherwise to go through a lengthy and costly selection process and workers who may lack the information on suitable jobs in the market. To be effective, job search assistance requires close links between employers, the intermediation office – generally public employment services and, increasingly in industrial countries, private agencies – and the job seekers. (See Immervoll and Scarpetta (2012) for a review of the effectiveness of active labor market policies in developing and emerging economies and Card et al. (2010) for a meta-analysis of the empirical evidence.)

Labor market training includes publicly supported programs, usually through either direct provision (in public training institutes) or financial support (funding training costs and/or subsidizing trainees). In many countries, governments are moving away from the role of direct provision of training and focusing more on addressing market failures in information and financing, while leaving more of the delivery to private providers. Job skills training have been shown to be quite successful in improving the chances of beneficiaries in securing employment (see, e.g., OECD, 2010a).

Training programs for youths, even when well-targeted, tend to have a poor track record. Interventions typically include some combination of on-the-job training, vocational (classroom) training, job readiness training, and/or internships. However, earlier interventions at the schooling stage are likely to be more effective than trying to remedy education failures (Betcherman et al., 2003) The experience of some Latin American countries offers some interesting insights. The

'Jovenes' programs in Argentina, Chile, Peru, and Uruguay are targeted at disadvantaged youth – combining training and work experience with other services including psychological development and vocational assessment (see OECD, 2010 for a review and OECD-ILO, 2014).

Reinforcing Self-Insurance among Formal Workers

In most low- and middle-income countries, mandatory severance pay provisions are the prevalent form of insurance against unemployment for workers in the formal sector. Generally easy to administer, the provisions exchange resources, in the event of unemployment, for an 'insurance premium.' Whether the premium translates into lower wages affects labor costs for firms and their incentive for hiring. But the schemes do offer a limited pooling of unemployment risk because they are firm-specific and because the premium generally evolves with tenure and not with the risk of unemployment. (De Ferranti et al. (2000) argue that, when Latin American countries had little exposure to foreign competition, the effective pooling of unemployment risk offered by severance pays was spread over a greater population, as consumers often times subsidize potentially bankrupt firms through higher prices. However, this possibility has declined rapidly as countries have embarked on trade liberalization and reforms aimed at fostering domestic competition.)

Severance pay provisions suffer from noncompliance in many countries, increasing workers' resistance to leaving a job. The risk of nonpayments tends to increase when financial resources are lacking because the firm is experiencing difficulties, or simply not be available if the firm goes bankrupt. Noncompliance also creates a burden on labor courts and government budgets. To tackle these shortcomings, some countries have introduced prefunding or reduced the generosity of payments to bring them more in line with international experience. Colombia moved toward a funded system under individual savings accounts in 1990, and Chile introduced a social insurance component to its system in 2002.

Workfare Programs to Combine Income Support with Improvement in Local Conditions for Investment

Workfare programs have traditionally been the most widely used form of intervention to support poor households and promote local infrastructure development. They generally transfer income to poor households, by providing unskilled manual workers with short-term employment on projects such as road construction and maintenance, irrigation infrastructure, reforestation, and soil conservation. In most developing countries, workfare programs have been used to smooth consumption and keep poor people in contact with the labor market (see Grosh et al., 2008 for a review). Well-designed workfare programs build much-needed infrastructure and thus minimize the trade-off between public spending on income transfers and on development. The National Rural Employment Guarantee Scheme, introduced in India in 2005, which provided 100 days of guaranteed paid employment to every household whose adult members volunteer to do unskilled manual work, while expensive has contributed to the local development of rural communities (see Dutta et al., 2012 for an assessment). Workfare programs have also helped many small private contractors to emerge and grow.

Conditional Cash Transfers to Fight Poverty while Supporting Human Capital and Health

Conditional cash transfers are another policy tool used to combine income support with local development. They belong to a family of transfer programs that combine close targeting with capital accumulation by making income support conditional on either basic needs triggers, such as utility offset payments (in some transition economies), or behavioral changes, such as the continued school enrollment of children or attendance at health clinics. They typically address chronic poverty rather than idiosyncratic risks associated with job loss. Their focus on human capital formation makes them suitable to address poverty and local development at the same time. In Mexico (Progresa, which reached 2.3 million families in 1999), Brazil (Bolsa Familia and PETI), and Jamaica (PATH), conditional cash transfers are largely used to promote health and human capital of children. The programs also tend to be better targeted than general subsidies by the use of proxy means testing and geographical targeting. They are highly transparent about who receives the transfers, and the level of benefits and the number of beneficiaries are easily adjusted in times of crisis. As with any transfer program, conditional cash transfers have problems, especially when the increased demand for services is not met by increased supply (schools or clinics) or when the targeting is not sufficiently resistant to outside influence.

Concluding Remarks

Over the past three decades, developing and emerging economies have undergone major changes in their economic and social systems; in many countries, economic growth has strengthened with significant effect on poverty reductions and improvements in the well-being of populations. These major changes have also been reflected in the labor markets; jobs have been transformed, skill demand has evolved dramatically, and more generally labor markets have been exposed to greater pressure to modernize and increase their adaptability.

No doubt, better labor market outcomes depend on a complex set of factors that shape the investment climate in each country and promote sustainable growth and job creation in the formal sector. Adequate labor market and social policies and institutions can play an important role to foster better outcomes for workers and their families. While many low- and middle-income countries have made significant progress in setting rules governing working conditions and the employer–worker relationships, the enforcement of these provisions remains often weak and uneven across sectors and firms. In this context, many firms opt out of the formal sector and remain uncovered to maintain profitability, facing great uncertainty in their labor relations and constraints in their growth and job creation potentials. Improving the institutional fit of labor regulations with the economic reality of the different countries – and in line with the international experience – is one of the main challenges of labor reforms in developing and transition countries.

Reforms of labor regulations will face large resistance and may not succeed if they are not accompanied by improvements in social protection mechanisms that cushion adjustment costs for affected workers. In many developing countries, this task is currently hampered by a narrow tax base. Most social protection schemes only cover formal sector workers – that is to say the non-poor – and do not offer adequate protection against job losses even amongst those with a formal job. Rural and informal workers are often under the threat of unexpected illness, job loss, or poverty in old age. There are clear opportunities for improving the insurance component in income support schemes for formal workers and the pooling of risks across individuals. And innovative programs can also reach out to poor and informal workers who cannot be covered by broader insurance schemes. For example, in a number of countries, some new forms of income support and job creation have tried to shelter poor workers from major income losses by providing targeted cash transfers and workfare programs. While greater resources and better targeting of social protection interventions toward the neediest people are warranted to promote labor market adaptability, a better prospect for the poor requires a comprehensive intervention in the investment climate that promotes growth and job creation.

Development and the State

Abstract

The state has long played a vital role in countries' development trajectories. Institutionally oriented economic historians (such as Polanyi and Gerschenkron), development economists (such as Hirschman, Amsden, and Sen), and development sociologists (such as Evans) have assumed development required active state involvement in constructing new institutions to facilitate trade and investment, and mobilizing resources in ways that accelerate the growth of new productive capacities. The record of East Asian developmental states from the 1960s through the 1980s vindicated this position. Neoliberal theorists saw the state as extracting rents in a self-serving manner, giving entrepreneurs the wrong incentives and impeding development. Predatory states were the empirical referents for their theories. Changes in the global economy and contemporary criticisms of development as insufficiently oriented toward the well-being of ordinary citizens, neglecting the importance of democracy, and failing to protect the natural environment present new challenges to states that are trying to be 'developmental.'

Over the course of the twentieth century, states' roles have broadened from the classical concern of making war and enforcing internal order to include creating the conditions for 'development.' The term 'development' became synonymous with the process of speeding up socioeconomic change, especially in the industrial sector, and registering macroeconomic results, particularly for countries in Africa, Asia, and Latin America. In other words, for much of the twentieth century, development meant the transformation of agriculture, the growth of industry, and a host of accompanying social, political, and economic changes. The role of the state in developmental success has been vital. However, not all states have played a developmental role, leading to the question, 'When and how does state behavior facilitate or impede development?' This question becomes even more acute today as the conditions faced by developmental states have undergone important changes in the last 20 years, making the tasks for states seeking development even more complex.

Historical Perspectives on the State's Role in Economic Transformation

Calling the poor nations of Asia, Africa, and Latin America 'developing countries' implies that they are undergoing economic and social transformations that mimic the experiences of the industrialized countries of the North. Understanding the role of the state in earlier periods of industrialization is, therefore, important to thinking about development and the state today.

Three streams of thinking are worth highlighting. First, there is the perspective of economic historians, such as Douglass North (1981), who see the provision of predictable norms and laws, particularly those that define and protect property rights, as the state's primary contribution to development.

The second view sees states as actively constructing new institutions to facilitate trade and investment and mobilizing resources in ways that accelerate the growth of new productive capacities. This view is epitomized in Karl Polanyi's (1957 [1944]: p. 140) classic statement: "The road to the free market [in England] was opened and kept open by an enormous increase in continuous, centrally organized and controlled interventionism." Alexander Gerschenkron (1962), looking at 'late developers' in Europe, reinforced and extended Polanyi's analysis by suggesting that countries like Germany and Russia faced a more difficult economic problem than England. They had to 'catch up.' By the time they began to industrialize, existing production technology required a scale that exceeded their societal capacities. Lacking both individual capitalists able to assume risks at the scale required by modern technology and private institutions able to spread risk, the state had to serve as investment banker or bear the risks itself, bringing together the necessary funds and encouraging their application in productive activities.

The third strand of thinking emphasizes the centrality of struggles over conflicting interests to the dynamics of development, the vital role of exploitation, immiseration and repression in the functioning of advanced capitalist economies, and the fundamental transformation of economic and political institutions globally. Within this Marxist critical political economy perspective, dependency theorists argued that late developers face historical disadvantages and unequal relations among nations within the world capitalist system (e.g., Frank, 1967; Dos Santos, 1970; Wallerstein, 1974; Cardoso and Faletto, 1979). Building on this framework and integrating it with elements of the institutionalist view above, scholars of 'dependent development' went beyond the structural determinism that negated the possibility of development in the Third World to suggest that states have a pivotal role as an agent of social control through three primary tasks: (1) it ensures a quiescent working class to facilitate industrialization; (2) it enlists multinational corporations to play a driving role in industrialization; and (3) it develops entrepreneurial initiative (Evans, 1979). (The term Third World emerged during the Cold War to distinguish between the First World (e.g., the capitalist West), Second World (e.g., communist East), and Third World (e.g., developing countries). Today, the term

Global South is used as it refers to a country's geopolitical position in the global capitalist economy, and not its geographic location. You can have countries geographically in the northern hemisphere, but part of the Global South (e.g., India), and countries geographically in the southern hemisphere as part of the Global North (e.g., Australia). I will use the corresponding term according to the historical period being discussed.) In short, states play the crucial role in coordinating and promoting national economic development.

Analyzing the State's Role in Third World Development

Perspectives, like those of Polanyi, Gerschenkron, and Evans in which development was not the spontaneous result of the activities of private economic actors but had to be explicitly fostered by the state, resonated in the Third World. In Asia, Africa, and Latin America, the gap between local capacities and the institutional scale required to be competitive with firms in the industrialized North was much bigger than the gap Russia and Germany had faced a century earlier. Local elites were too often wedded to maintaining agrarian structures that preserved their privilege at the expense of national productivity. The fact that the United States and Europe were just emerging from a period in which substantial increases in state intervention, first to combat the Great Depression and then to mobilize for World War II, made this perspective even more plausible.

Development Planning, Import Substitution, and Entrepreneurial Initiative

The conviction that Third World countries could not develop unless they managed to escape their traditional dependence on exports of agricultural products and raw materials was a key impetus to increased state involvement. Manufacturing products locally rather than importing them was seen as a central part of development, and emerging local manufacturers needed protection from established rich-country firms, if they were going to succeed at this process of 'import-substituting industrialization.' They also needed public investments in energy production and transportation. Deciding which of these investments made sense required planning. Private investors also faced a collective action problem. Investment in manufacturing would make more sense if other local entrepreneurs were making complementary investments that would provide needed inputs. Active state involvement was a way of giving entrepreneurs confidence that they were part of a general, mutually reinforcing set of investment decisions.

Without advocating expansion of the state's role, Albert Hirschman was one of the most creative contributors to thinking on these issues. Hirschman carried Gerschenkron's argument a step further, arguing that a dearth of entrepreneurship in the simple sense of "the perception of investment opportunities and transformation into actual investments" (Hirschman, 1958: p. 35) stood in the way of "late late industrialization" more than the lack of capital. The state could help induce private capital to become more entrepreneurial by providing incentives that made decisions harder to avoid. In Hirschman's view, inventing a national project of entrepreneurship is the key to development and the state can be an important participant in the process of invention.

Neoliberal Critiques of State Intervention

Import-substituting industrialization and the state involvement that went with it resulted in impressive rates of economic growth during the 1950s and 1960s in countries ranging from India to Brazil, but by the end of the 1970s development strategies in Africa, Latin America, and South Asia were in disarray. Imports were growing faster than exports, creating balance of payment problems, and state expenditures were increasing more rapidly than revenues, creating fiscal problems. One of the responses to this disarray was a renewed interest in the state on the part of neoclassical political economists.

Like Marxists, neoclassical political economists saw the state as the instrument of special interests rather than universal ones. Unlike Marxists, they applied the utilitarian logic of individual maximization to actors within the state itself. They saw the state extracting rents and giving entrepreneurs the wrong incentives rather than solving collective action problems and inducing more entrepreneurship. Theorists like Anne Krueger (1974) applied this logic to strategies of import-substituting industrialization, arguing that the desire to gain protection from foreign competition led entrepreneurs to focus on the unproductive quest for state favors rather than on competitiveness. Studies like Robert Bates' (1981) analysis of the perverse effects of state intervention on the development of African agriculture helped build the case that there were serious problems with earlier optimistic visions of the state's role in development.

These critiques had some merit. Development planning had indeed presumed an unrealistically benign state, ignoring the self-seeking behavior of state elites. Corruption was rife in developing states. Entrepreneurs in industries like textiles did indeed continue to demand that indulgent states provide them with protection long after they should have become mature and internationally competitive. This negative neoliberal image was best characterized by predatory states with their self-interested elites who extract society's surplus wealth and income, use it for their own benefit, and provide so little in the way of collective goods in return that development becomes impossible. Zaire under the rule of Mobutu in the 1970s and 1980s was a classic example. Under Mobutu, the income of Zaire's citizens shrank at over 2% a year, while state officials acquired multiple European mansions and Swiss bank accounts. Nonetheless, these neoliberal theorists lacked good answers as to how developing countries could overcome the weaknesses of their private entrepreneurial classes and self-serving state elites. Ironically, the policy prescriptions of the neoliberal paradigm actually reinforced the dynamics of predation as state and economic elites were released from the obligation of national development. The state's role was now focused on unleashing and deregulating markets, dismantling industrial and social policies, privatizing state assets, and removing barriers for imports. For the predatory elite, these were ideal conditions, as they were now free to pursue profits

unencumbered by the responsibility of providing collective goods and pursuing national economic development. Moreover, neoliberal theorists also failed to acknowledge that there were important variations, even among poor countries, in the behavior and capacities of states.

The Developmental State

For most states, the neoliberal view is partial and misleading. The state apparatus may extract, sometimes corruptly, but it also provides essential collective goods without which development could not proceed. Most interesting is the subset of states that are able to foster long-term entrepreneurial perspectives among private elites, help solve collective action problems, and supply essential public investments in education and infrastructure. The elites that control these states may not be immune from using society's surplus for personal ends, but the nations they govern enjoy faster rates of economic development because of the collective goods they supply. This category of 'developmental states' is best illustrated by looking at East Asia from the 1950s through the 1980s.

The East Asian 'Miracles'

The rise of East Asian economies further illuminated the role of the state in achieving development. In his study of Japan's Ministry of International Trade and Industry (MITI), Chalmers Johnson (1982) coined the term 'the developmental state,' which was almost immediately picked up and used in seminal studies of other newly industrializing economies (e.g., Amsden, 1989; Wade, 1990; Woo-Cumings, 1991; Evans, 1995). Japan's successful challenge of the industrial supremacy of Europe and the United States in the 1950s and 1960s was followed by the developmental success of South Korea, Taiwan, and Singapore. These countries grew six times faster than the advanced industrial countries had grown in the nineteenth century during the industrial revolution. They are unique in the Third World in the degree to which they have managed to change their position in the world economic hierarchy. These states are considered developmental, not just because the nations they governed grew but because the transformation involved in that growth was directly related to the behavior of the state.

The Analytical Characteristics of the 'Developmental State'

Starting with Johnson's (1982) analysis of the Japanese case, a variety of analysts have tried to specify what makes states developmental (see, for example, Amsden, 1989; Wade, 1990; Chang, 1994; Evans, 1995; Akyüz, 1999; Chibber, 2003; Kohli, 2004). While there has been much debate, there are surprising elements of consensus that extend into mainstream development economics (see Meier and Rauch, 2000: Chapter 9) and the international policy community (see World Bank, 1997). Among the essential structural features is a capable and coherent state bureaucracy that is connected to, but still independent from, various social forces and in particular the economic elite. An effective and independent state bureaucracy is necessary in order to sagaciously pursue economic policies in the national interest. Links to the industrial class are equally essential in order to persuade them to invest in key sectors of the economy and in collective goods. At the same time, the autonomy from the economic elite is vital so that the state can pursue national interests unencumbered, or without being captured, by private interests. Maintaining 'embedded autonomy' is pivotal for developmental success (Evans, 1995). The roots of such capable bureaucracies lie, in turn, in mechanisms familiar to students of Max Weber such as meritocratic recruitment and public service careers that offer long-term rewards commensurate with those available in the private sector.

The policies of developmental states mirrored the behavior Gerschenkron and Hirschman argued was needed in order to promote late industrialization. Investments in essential modern infrastructure, such as telecommunications, helped to set the stage for industrial growth. Entrepreneurs were induced to make long-term investments that raised national productivity. Subsidies and selective protection against external competition led to the creation of industries like semiconductors, steel, and shipbuilding that private entrepreneurs would never have embarked on without state support. Linked to this is the state's capacity and willingness to discipline capital if it fails to deliver on its end of the agreement (i.e., the state provides subsidies and protection in return for productive investment in targeted sectors). Exports, overall output, and real wages all grew at unprecedented rates. Public investments made rapid rises in education levels possible and health measures, such as infant mortality levels, improved. In short, essential features of the developmental state include a coherent and effective bureaucracy with the capacity to discipline capital, extract revenues through taxes for investment in public goods, provide an environment of rule of law, create appropriate policies, attract investment, protect industries, and encourage exports.

Contemporary Issues and Future Directions

Beginning with the East Asian financial crisis of 1997–98, the efficacy of the developmental state was brought into question. Current thinking about development and the state raise at least four different challenges. First, the evolution of the global political economy has brought into question (1) the capability of individual states to shape developmental trajectories and (2) the focus on manufacturing-based industrialization. Second, economic development saw the concomitant rise of powerful and militant labor movements that placed increasing pressure on states to democratize. State–business linkages that were the hallmark of the twentieth-century developmental state have to be reconceptualized to include relations with wider society. Third, in an even more fundamental challenge, the unidimensional understanding of development as economic growth has been broadened to include understandings of human well-being. Linked to this, the validity of traditional strategies of development is increasingly contested. And finally, the ecological crisis has put a fundamental challenge to fossil-fuel-based industrial development. In combination, this questioning suggests a redefinition of the role of the developmental state.

Globalization, Economic Restructuring, and the Role of the State

The reorganization of production, and more crucially finance, around global networks, in combination with the increasing hegemony of market-oriented Anglo-Saxon ideology and legal norms, makes traditional industry-focused state strategies more difficult, even when these strategies combine import substitution with export promotion, as in the case of developmental states. Even though global organizations, such as the World Trade Organization, continue to depend on the institutional capacities of individual states to implement global governance rules, the leeway that states have in making their own rules to increase local entrepreneurship has been restricted. Even developmental states have felt the effects of globalization.

In addition, in recent years there has been a transformation of the world economy from the predominance of mining and manufacturing to the high-value, information-intensive knowledge and service sectors. The knowledge economy is an infinitely more complex terrain for economic policy-makers than an economy based on manufacturing. For countries in the Global South that seek development, a shift to knowledge and service sectors will be a necessary ingredient for their success. This means that the traditional emphasis on machine production and a manufacturing-based economy (i.e., the physical production of tangible goods) must be supplemented by a turn to the more complex and innovative sectors of knowledge and service. Growth is increasingly found in 'bit-driven' information, and technology such as software codes, images, and formulas, and the state's role is even more important but vastly more complicated (Evans, 2014; Ó Riain, 2014; Wang, 2014).

The Crisis of the Developmental State and Expanded Embeddedness

The dominant tenor of first reactions to the 1997–98 Asian financial crisis was that either globalization has turned the developmental state into an anachronism or it was a hoax to begin with. More sober reflection produced a different diagnosis. One of the lessons of the crisis was that states cannot afford to relinquish controls over international financial flows before constructing appropriate mechanisms for regulating national financial markets. Abandoning its previous role, not clinging to it, was the developmental state's failing. This failing did not result simply from the pressures of globalization. It also reflected a change in the politics and policies of the developmental state itself. Having achieved impressive gains in global markets, local corporate elites were less likely to believe that a coherent, capable state bureaucracy was relevant to their success. Global ideology favoring the dismantling of the state's regulatory capability also became more popular within the state apparatus. Even though financial stability and growth were restored with remarkable rapidity, the crisis revealed that, precisely because of its economic success, the state's alliance with private capital was no longer likely to produce the same developmental results.

At the same time, the exclusive focus on state–business relationships and states' repressive stance toward organized labor unleashed protests that were increasingly difficult to restrain (see, for example, Lee, 2014 for a discussion of China). Indeed, various country experiences suggest that economic growth has brought about demands for more democratic participation, or an 'expanded embeddedness' beyond the developmental state's narrow alliance with the business elite. Sen (1999) captures this shift by highlighting that democracy is both a goal of and means to development. While both representative and direct democracy are vital components of democracy, Sen highlights the importance of direct democracy for ordering public interests and promoting effective citizenship (see Kerstenetzky, 2014; Isaac, 2014). Since the 2008 economic crisis in the Global North, calls for greater participation of ordinary citizens and increased state involvement in regulating economies have intensified. In short, expanded embeddedness and deepening democracy seek to increase society's power in relation to the state and capital. At the same time, the 'accumulation-oriented' definition of development that had formed the basis of the state's alliance with capital was increasingly criticized.

The Contested Definition of Development

The strategy of the developmental state, like the strategy of import-substituting industrialization before it, was built on the premise that investment in local manufacturing would produce jobs and that the incomes from these jobs would generate widespread increases in well-being. There have always been critics of this view, but recently they have become more vociferous (e.g., Evans, 2014; McMichael, 2007; De Sousa Santos and Rodriguez-Garavito, 2006; Escobar, 1995; Sachs, 1992). Critiques suggest that as manufacturing becomes more capital intensive, manufacturing investment consumes a disproportionate share of the social surplus relative to the number of jobs that results. Even when the money incomes of some ordinary workers do increase, improved overall well-being is not necessarily the result. Their ownership of more consumer goods does not compensate for the environmental degradation, increasing inequality, and destruction of intangible social and cultural assets that accompany the accumulation of productive capacity. For too large a proportion of the citizens of poor countries, the new global cornucopia of heavily advertised consumer goods remains beyond economic reach but still devalues prior cultural and social satisfactions.

While such perspectives may ignore the benefits of investment in productive capacity, they have contributed to the challenges of defining development exclusively in terms of accumulation and economic growth. As a result, the ideational understandings of development have experienced revision from a singular concern with economic growth to a more encompassing goal of social and human development. Thus, development has become more complex and multifaceted to include quality of life issues and noneconomic indicators (Sen 1995, 1999, 2001). (The idea of a 'happiness index,' first pioneered by the Kingdom of Bhutan, is also an effort to move beyond economic indicators of development.) A new generation of theories have emerged that include the 'basic needs approach,' which looks at social services (e.g., adequate food, clean drinking water, decent shelter, education, and security of livelihood) as a means for poverty reduction (Burki and Ul Haq, 1981; Melkote, 1991), the 'new growth theory' and the

human capabilities approaches both of which highlight investment in education, ideas, and democratic processes as a means for economic growth (Evans, 2014; Helpman, 2004; Sen, 1999; Romer, 1990, 1994). In short, the accumulation-oriented definition of development has been fundamentally challenged, both empirically and ideationally, leading to more encompassing and complex understandings of development.

Ecological Crisis and Development

In addition to the above challenges, ecological issues were not even defined as a problem at the start of the twentieth century, but now are considered to be one of the most important challenges states face (Harriss-White, 2014; Satgar, 2014; Castells, 2010; Peet and Watts, 1996). Development has been predicated on fossil-fuel-driven industrialization, using enormous resources and creating vast amounts of pollution and waste that most severely affect citizens in the Global South. Would-be developmental states of the twenty-first century have to find new ways of developing their economies that do not intensify the destruction of the natural world, including investing in renewable forms of energy. There are also calls not just for the protection of the environment but also to ensure that resources are used more equitably for the benefit of all and not just an elite few both within countries and among countries (Cock, 2010). The ecological question will certainly be one of the most important challenges for states seeking development for the foreseeable future.

Redefining the State's 'Developmental' Role

The changes in the goals of development and the conditions under which it occurs have posed fundamental challenges to the state's role in development. If development is really about well-being rather than about accumulating industrial capital, then what is the role of the state? A 'well-being-centered' redefinition of development implies a more aggressive focus on the state's traditional role in delivering collective goods and services, like health, education, clean air, water, and sewage disposal, and in preserving the collective environment, both natural and cultural, as well as promoting democratic participation of citizens. The kinds of state behavior and structures required by this redefined developmental role are surprisingly consistent with early pre-neoliberal thinking. Hirschman's notion of inducing decision-making among private economic agents becomes an even bigger challenge if the focus is on the provision and preservation of collective goods. Finding ways to convince entrepreneurs that they should invest in clean production techniques or take into account the social impact of investment decisions requires much more skill and capacity than helping them increase their profits through subsidies and protection. A would-be developmental state today must have the capacity to do the tasks of the twentieth century, but also add a commitment to human well-being, democratic participation, protection of the environment, and greater equality. At the same time, the conditions of the global economy have created a more complex environment under which states must pursue these goals. The greater magnitude of the challenge makes the emphasis on a capable, coherent, yet innovative and responsive to citizen engagement, state bureaucracy, which is central to thinking about the developmental state, more important than ever.

The biggest single change implied by this redefinition is already foreshadowed by the crisis of the developmental state. State–society relations dominated by close ties to industrial elites at the expense of other social groups provide neither the political will nor the societal collaboration necessary to execute a 'well-being-oriented' strategy of development that includes care for the natural environment. A more broadly defined set of state–society relations is imperative. There are some studies of the role of more broadly based state–society ties in promoting development (e.g., Isaac, 2014; Kerstenetzky, 2014; Heller, 1999; Evans, 1996), but extending and deepening this kind of analysis is the most obvious challenge confronting contemporary work on development and the state.

Abstract

This article examines the interrelationship between economic prosperity and the growth of cities, tracing the field from its original preoccupation with overurbanization and underdevelopment in the 1950s and 1960s to its current fixation on dynamic global cities with redeveloped property markets that showcase new forms of wealth creation. The historical change in emphasis chronicled here is understood to be combined product of three different causalities. The first is the shift from industrialization to financial and other services as the principal source of wealth creation in the post-1980s era. The second is the changing territorial scale of accumulation, reflected in the shifting importance of global markets vis-à-vis national markets and in the increasingly key mediating role that cities play in facilitating this transition. The third is the rescaling of state power, seen not just in terms of decentralization but also in the declining capacities of national states to discipline global investors in an era of intensifying economic liberalization. The article ends with a discussion of the emergent social and spatial problems that accompany these shifts, ranging from the rise of urban informality to dispossession and displacement to newfound struggles over urban property rights.

Economists, sociologists, political scientists, and anthropologists as well as demographers and planners have long theorized a direct connection between national development, understood economically and/or politically, and the growth of cities. But there has been little consensus about the nature and direction of the relationship, the desirability of analytically linking these processes, and how to define both terms. Reigning ideas have shifted in the face of new theoretical paradigms and as the territorial scope and essential character of markets, states, and cities themselves transform. Unresolved issues include which urban dynamics most enable or constrain developmental patterns, and whether the global phenomenon of rapid urbanization, intensifying economic globalization, and worldwide population concentration in cities have changed our theoretical or empirical understanding of these processes.

Historical Antecedents

Most scholarship on the relationship between development and urbanization traces its intellectual origins to writings by nineteenth- and early twentieth-century sociologists and economic historians who sought to account for the development of capitalism, the nation-state, and social modernization in early Europe, and who posited a direct and positive role for cities in these fundamental transformations (*see* State Formation, Theory of; Modernization, Sociological Theories of; Capitalism).

Cities and Development in the Early Modern World

In early modern Europe, cities emerged from and fueled processes of capital accumulation, by virtue of their role as exchange nodes in local, national, and international trade (Pirenne, 1936; Weber, 1927). Their growth also was tied to the demise of feudal or absolutist orders (Weber, 1958) and the rise of the modern nation-state (Tilly, 1975). By the late nineteenth century, cities also served as the sites in which the social relations of modernity materialized (Durkheim, 1933; Simmel, 1950), in turn transforming markets and states.

Twentieth-Century Developments

In the twentieth century when nationalism, war, empire, trade, democracy, and fascism required European attention, many US scholars turned to the study of cities. This was a time when American society demographically tipped its balance to become more urban than rural, and when new waves of postwar black migration combined with renewed streams of international migration to spark interest in the social relations of urban life. Initial research concentrated on the social process and experience within cities, ranging from ghetto life, immigrant social clubs, and gang organization to criminality. Few social scientists chose to examine the larger political and economic processes that engendered patterns of urbanization in the US, as occurred among European urban scholars; and even fewer tried to link urbanism or urbanization to patterns of national development, understood either politically or economically. It was only when US sociologists began studying cities comparatively and historically, starting in the 1950s and during a period of post-WWII expansionism, that debates over the relationship between development and urbanization garnered a central place. When the March 1955 (Vol. 60, No. 5) edition of the *American Journal of Sociology* published an entire volume on 'World Urbanism', the importance of these themes was firmly established.

The desire to examine other parts of the world was partly grounded in a passion for testing ideas drawn from the European-derived grand theoretical narratives of sociology. Practically the only counterfactual cases available for confirming prevailing propositions about the connection between urbanization and developmental progress – whether understood in terms of democratic state formation, capitalist development, and/or 'modern' social values – were the countries of

the so-called underdeveloped world of Latin America, East Asia, and Africa. These were countries of the world racked with poverty, limited industrialization, and governed primarily under oligarchic pacts or by despotic or authoritarian governments (*see* Attitudes Political: Authoritarianism and Tolerance). To the extent that their urbanization patterns also differed across country contexts, scholars were inspired to revisit general claims about development and urbanization, as well as to ascertain how these two processes were articulated in practice.

Working under the influence of the Chicago School, initial scholarship on what were then called Third World cities focused primarily on the folk-urban continuum and urbanization as a social process, including the ways that urbanization produced individualism and severed kinship bases of social organization (see, e.g., Hauser, 1957; Redfield, 1941, 1953). Over time, interest grew in urbanization as a demographic and spatial process, with scholars examining patterns of population concentration and the growth of cities in a wide variety of comparative and historical contexts (Berry, 1973; Hauser and Schnore, 1965), occasionally linking them to general propositions about national development. In addition to Hauser and Schnore's seminal *The Study of Urbanization* (1965), the Chicago-based journal *Economic Development and Cultural Change* served as an important outlet for new ideas on the topic.

Twentieth-Century Dilemmas: Questioning the Nature and Direction of Causality

It was one thing to quantify urban population patterns across time and place (Davis, 1969; Hoyt, 1962), to identify the extent to which urbanism, as a social attribute, materialized in different localities around the world (Breese, 1966; Mangin, 1970), and to elucidate growth processes in these cities (Gugler, 1978; McGee, 1971). American social scientists were quite good at these tasks, especially the first; and their successes helped catapult the field of demography onto the disciplinary map in the 1960s and 1970s (see, e.g., Goldscheider, 1971; Goldstein and Sly, 1979). It was quite another to demonstrate a direct relationship between urbanization and patterns of economic development, especially within the confines of the nation-state, the unit that most social scientists were then using for assessing such issues. It was on these latter counts that scholars were least successful, and that longstanding propositions about the positive relationships between urbanization and national development began to generate widespread skepticism.

As Third World cities burgeoned over the 1960s and 1970s, scholars faced the fact that even with high urbanization rates, developmental gains in most of the late industrializing world remained minimal, not just in comparison to the modal patterns established in Europe and the United States, but also as measured in per capita income, gross national product, and practically all other standard macroeconomic indicators (Friedmann, 1967). With dependency theory taking center stage at about the same period of time, certain attributes of both urbanization and national development were thus traced to colonial or mercantile relations that spanned national boundaries rather than to political, social, and economic conditions within the formal confines of the nation-state (*see* Dependency Theory). These transnational relations modified urbanization and development processes, at least when compared to early modern Europe, even as they raised new questions about the best unit of analysis to study the nature and direction of the proposed relationship. Did urbanization husband development, or vice versa; and was it possible that in the late developmental context the relationship between the two sets of processes was more likely to be negative than positive, with one impeding rather than facilitating the other? The answers to these questions shifted over time.

Development and Urbanization *c.* 1950: A Positive Synergy

The predominant argument in the 1950s and early 1960s was that the plight of developing nations and their low rates of urbanization owed to their 'backward' social and economic nature, which not only explained why industrialization was minimal, but also why tradition-bound peasants demographically outbalanced 'modern' urban folk. Analytical attention was directed toward how to facilitate one so the other would follow suit, a normative preoccupation pervasive in American social science and quite consistent with US foreign policy goals of the times.

There were disagreements about which domain deserved intervention first. Some urban scholars argued that the best way to jump-start Third World development was to shift population and resources out of the countryside and into the city, where industry could expand and modern values flourish (Herrick, 1965; Field, 1970). Others called for more foreign aid or national investment to buttress urban economies, primarily through industrialization (Richardson, 1973), in the hopes that such macroeconomic policies would stimulate employment opportunities and perhaps even produce individuals inculcated with rationality and enough achievement drive to sustain further urban and national gains (*see* Industrialization). Despite policy disagreements, both schools of thought expressed enough faith in the idea of a positive relationship between development and urbanization to keep it alive, albeit embodied in a variety of paradigmatic forms.

Over the 1960s and 1970s, one particularly popular variant was demographic, as those interested in urbanization as a social process looked for linkages between urban growth and national development in fertility patterns as well as family structure and employment. During this period ideas about the demographic transition, at times recast in terms of the 'urban transition' (Friedmann, 1975), generated considerable interest among economists and sociologists, who developed expert quantitative skills that sustained a field of research broadly understood as 'population studies'. Those less preoccupied with the social or economic behavior of individuals and more interested in overall patterns of city growth and distribution were more likely to concern themselves with ideas about the proper balance between urban and rural populations (El-Shakhs, 1974; Friedmann and Alonso, 1964).

During this period, scholars who assumed that the US served as a model of successful economic development paid

considerable attention to the extent to which urban systems in developing countries achieved a lognormal rank-size distribution, as opposed to being dominated by one or two large 'primate' cities (Berry, 1961), basing their interest on the assumption that rank-size lognormality correlated with economic development. In counterattack, these ideas were criticized as inherently Western-biased, if not drawn directly from the American experience, and thus inapplicable in the Third World (El-Shakhs, 1972; McGreevey, 1971). While there was no resolution on this contentious issue, in the process the concept of 'overurbanization' gathered widespread attention, since a city could only be 'too' urbanized if it grew beyond its expected and economically efficient size, which often was calculated on the basis of a rank-size distribution logic.

To the extent that most Third World countries fell into the latter camp, with their cities ballooning in size beyond their fiscal and infrastructural capacities, scholars began to study the internal social and demographic processes that fueled patterns of overurbanization, and what Michael Lipton (1977) called 'urban bias', including rural–urban migration and the national investment decisions that over privileged a few urban centers at the expense of struggling provincial towns and the impoverished countryside. Still, concerns about city systems died hard, rematerializing in slightly new packaging in the 1980s in the form of arguments about the importance of 'secondary cities' to sustaining national development (Hardoy and Satterthwaite, 1986; Rondinelli, 1983). This claim, like the rank-size distribution argument, was built on the understanding that (smaller) size and (more equal) distribution of cities mattered; and both arguments confirmed the preoccupation with a relationship between patterns of urbanization and development that had initiated and sustained the field.

But far from merely confirming a connection between cities and national development, these findings laid the foundation for an immanent critique of long-standing claims. Indeed, to the extent that the burgeoning growth of Third World cities was soon seen as an obstacle to economic well-being, there was now evidence that a positive relationship between urbanization and development was effectively reversed on substantive grounds, even if analytically the connection remained. To be sure, there were scholars who conceived of large cities as economically efficient localizers of economies of scale, and they continued to claim a positive relationship between large-scale urbanization and development (Richardson, 1973). But by and large, promoters of this idea were arguing against a tide of contrary evidence.

Development and Urbanization, *c.*1975: A Destructive Relationship

The ascendance of ideas about a negative relationship between urbanization and development owed partly to the fact that between 1950 and 1975 conditions in the developing world changed dramatically. This was the period when most Third World cities began to grow enormously, outpacing the capacities of their governments to invest in infrastructure or sustain industrial output in ways that contributed to national development. With large cities peopled by new migrants and un- or underemployed folk with limited education and skills for a newly industrializing economy, they soon were seen as a drain on national coffers. The increasing urban inequality and economic polarization accompanying these trends also sustained urban social movements and overall political coalitions that themselves limited national developmental prospects by bringing to power governments with restrictions on foreign investment, populist economic policies, and/or protectionist measures that frequently undermined short-term efficiency goals. These social and political problems became so salient in the urban landscape of the developing world that eventually scholars turned attention directly to them (see Abu-Lughod and Hay, 1977; Gugler, 1988; Mangin, 1970), partially eclipsing the concern with national development. Among the most documented issues were urban housing and employment scarcities, rural–urban migration flows, illegal settlements and urban 'marginality,' and migrant or informal sector politics (Cornelius, 1973; Drakakis-Smith, 1987; Perlman, 1976).

This is not to say that all those who looked internally to cities over the 1970s and 1980s failed to examine the larger relationships between urbanization and national development that had consumed their predecessors. Economists at the World Bank and other macroeconomic policymakers loyal to free market ideals continued to study urban economies of scale and the ways urban growth interfaced with industrialization, still seen as the principal route toward prosperity; although they too concerned themselves with questions about housing, illegal settlements, and urban service scarcities more generally (Linn, 1983). Likewise, but on an entirely different front, sociologists and political scientists began to examine the national political conditions that made these urban problems so pervasive (Eckstein, 1977; Gilbert and Ward, 1985; Rabinowitz, 1973; Roberts, 1978). But this also meant that urban scholars were focusing as much on political as economic developments, linking urbanization patterns to national politics as much as markets (*see* Populism).

When dependency theory emerged as a dominant paradigm among both resident and foreign scholars of the developing world over the 1970s and 1980s, fewer scholars began to pose questions about the relations between urbanization and national development unless they were framed within a focus on international economic conditions (Castells and Velez, 1971; Portes and Walton, 1981; Walton, 1985); and even fewer saw the articulation of urban and national development in positive terms, as had their predecessors. If anything, when urbanization was linked to capital accumulation, the social effects were seen as relatively negative (Armstrong and McGee, 1985). By the late 1980s, the main idea in good currency was that capitalist development on a global scale produced and/or reinforced mercantilist relations that fueled the growth of cities, even as they disadvantaged the countryside or the nation as a whole.

Using a global framing, scholars focused not just on the ways that unequal, semi-imperial relations between core and periphery brought a few large cities, themselves parasitic with respect to their hinterlands. They also examined the ways these relations produced a form of 'internal colonialism' predicated on extreme income and investment polarization between city and countryside, which further fueled migration,

contributed to overurbanization, and reinforced income and other inequalities within cities themselves (see Timberlake, 1985). The argument for a negative relationship between urbanization and sustained or autonomous national development thus reached new heights of acceptance (*see* World Systems Theory).

Development and Urbanization, *c.*1990: Disarticulated Processes

The growing popularity of world-system theory over the 1980s and 1990s may have strengthened scholars' understandings of the strong connections between urbanization and (under) development (Smith, 1996); but in the long run it contributed to the analytic disarticulation of cities and nations, thereby casting a mortal blow to studies of relations between these two domains. As scholars joined the world-system bandwagon and bypassed the nation-state as a unit of analysis, few examined national development as analytically distinct from global processes. Those development scholars who did concern themselves with the domestic dynamics of macroeconomic development rarely reserved a place for cities in their analytic frameworks, turning instead to states, classes, and the global economy. The result was that scholars who analyzed cities in the developing world did so increasingly in the context of global economic conditions (Friedmann, 1986; Abu-Lughod, 1989), even as most scholars of national development ignored cities by and large.

This analytic disarticulation of urbanization and national development was further fueled by intellectual and political dynamics in the developing world. With many countries in Latin America, Africa, and Asia becoming less democratic and more authoritarian throughout the 1960s and 1970s, their states became stronger and more repressive. These political regimes tended to privilege capital over labor and cities over the countryside, using macroeconomic policy, national investments, and targeted subsidies to accomplish these aims. Resident and foreign observers saw little autonomy for cities, with urban development mostly dictated by powerful (if not militarized) national states. This was most evident in the largest cities, home to their nation's most significant industries and investments; but it also was seen as a pattern more generally. The result: in studies of the Third World, urban dynamics were frequently subsumed under national ones. This conceptual sleight of hand may have reinforced views about the direct relationship between city and nation to some extent; but it also chipped away at the analytic distinction between urban and national dynamics. And with these two processes increasingly collapsed into each other, the tendency was to examine one or the other, but not the interactive relationship between the two.

Among the few still fervently examining the direct connections between urbanization and national economic development were neoclassical economists, along with World Bank staff and their clients. They worked under the supposition that by facilitating and/or managing cities, national actors could ensure productivity, efficiency, and the flow of people and goods sufficiently to maximize overall development. Yet in most of the nonapplied fields, urbanists and developmentalists hardly spoke to one another.

A New Articulation (or, Development and Urbanization in the Age of Economic Globalization)

By the turn of the millennium scholars began to widely accept the premise that globalization ought to be viewed as a central point of entry for studying changes in the contemporary world, thus bringing about renewed interest in the urbanization-development nexus. Initially, scholars became fixated with cities of enormous size and importance, whose growth and character owed to the role they play not just within their national borders, but also within global networks of production and consumption (Henderson and Castells, 1987; Lo and Yeung, 1998; Sassen, 1991, 2000). This realization also produced a shift in terminology. Few scholars referred to Third World cities anymore, preferring instead 'cities of the global south' (or north) or the concept of world or global cities, both in recognition of the unequal world distribution of production and consumption wealth. The idea of world cities was not new of course (Friedmann and Wolff, 1982); and much of the work drew inspiration from earlier writings on overurbanization in Third World cities in which the inflated size and rapid growth of primate cities was linked to unequal relations of exchange between so-called core and peripheral economies. But as economic globalization continued to bring rich and poor countries into the same orbit, scholars were more willing to think about cities in global rather than national context, hence the popularity of world or global city nomenclature. Similarly, world cities were less likely to be seen as fetters on the national development of their host countries, and more likely to be perceived as the mechanisms through which global economic integration took root.

Such views not only challenged the dependency era understandings of the destructive impact of global dynamics on cities and nations, they were also accompanied by a new geographic focus among urbanists. Over the period 1960–2000 most scholars interested in the urbanization-economic development nexus examined the poorer countries of the global south; but by the 1990s the US and Europe were back in the center of the conceptual map (King, 1990; Sassen, 1991), with cities like New York, London, Tokyo, and Paris taking center stage as global cities where urban employment patterns, shifts in sectoral character, and spatial forms were seen as products of the globalization of capital and labor (Fainstein et al., 1992; Sassen, 1991). The analytical focus also produced a renewed interest in the changing 'locations' or economic roles these cities played in a regional, national, or international hierarchy of urban places (see Knox and Taylor, 1995).

But as the global system of world cities itself began to transform, new questions began to emerge as to whether those cities with the greatest potential to generate national or even international developmental gains were indeed sited in the advanced capitalist world (see Robinson, 2002; Gugler, 2004). Such queries have arisen in response to rapid and concentrated urbanization of cities in the emerging economies of India, China, Brazil, and other formerly poor regions where rapid and concentrated urbanization has been accompanied by massive wealth creation for individuals, urban authorities, and national accounts. As some scholars turned

their attention to these urban transformations, chronicling the new cadre of city builders responsible for jumpstarting formerly lagging economies through global city branding (Ren, 2011), others began to criticize the rush to find new ways of categorizing cities in terms of their paradigmatic status (Beauregard, 2003; Brenner, 2003; Roy and Ong, 2011). Among those most willing to jettison superlatives and theorize cities in more 'ordinary' terms (Robinson, 2006) were those who also were willing to recognize that even the most prosperous cities in the late developing world still hosted high degrees of poverty, inequality, and extraordinarily high degrees of economic informality. As such, even with focus shifting to formerly poor regions of the world, questions persisted about nature of the relationship between development and urbanization, and whether the latter could really be seen as a route to prosperity if the scale of the city remained the unit of analysis.

Development in the 'Urban Century': Are Cities Leaving Nations Behind?

Though exact projections differ, it is widely accepted that the global population reached and surpassed the demographic tipping point to become majority urban in or around 2008 (Satterthwaite, 2007). Within the contemporary study of urbanization and development, the more significant trend may be that nearly all population growth projected to take place globally over the next 30 years will be in developing-world cities throughout Asia and Sub-Saharan Africa and that this growth is unlikely to slow significantly before 2030 (United Nations, 2012). Due to the high level of variation in national and subnational development trajectories throughout these regions, most notably between the comparatively high-performing economies of countries such as China, India, Singapore, and South Korea, and economically stagnant, but rapidly urbanizing countries of Sub-Saharan Africa, two distinct analytical frameworks have emerged within the current study of the development-urbanization nexus: one continues to articulate the role of cities and agglomeration economies as the principle drivers of economic and social development, while the other calls attention to the significant social and environmental costs associated with rapid and often unplanned urbanization.

Those who argue that cities are the privileged sites for economic development have brought new analytical rigor to the debate by focusing on how urbanity unleashes creative potential through agglomeration and the spillover effects of knowledge economies in developed and developing world cities alike. These ideas, gaining popularity among economists in particular, view the proliferation of urban slums in the developing world not as markers of systemic weakness, but rather of 'the city's' ability to attract rural poor through the promise of improved livelihoods and health (see Glaeser, 2011). In the developed world, attention is shifting to economic clusters in key cities or areas within them, with research suggesting that such experiments can support new, creative economies in previously declining, postindustrial cities and regions of the United States and Europe, thus reenergizing the study of the urban-economic development nexus at a scale smaller than the nation (see Porter, 2003).

As a sign of the globalization of ideas, cluster theory also migrated to the developing world, particularly in East Asia where bottlenecks among export-led industrializers pushed their national governments to invest in industrial clusters outside major cities. But the theoretical and practical significance of cluster theory in the developing world has been slow to gain a foothold in the face of the increasing national obsession with producing global cities that can showcase high-end real estate, global finance, and ICT activities, all considered the principal avenues through which cities and their nations were to prosper economically (Olds, 2011).

The preoccupation with finance, services, communications, and other tertiary sector activities can be explained by international capital's search for new investment outlets in the face of declines in industrial and agricultural output. Yet it also captures the imagination of investors – both public and private – in emerging economies that seek to generate national economic gains through more than export-led industrialization or agriculture. The cases of China and India are exemplary in these regards. In these and a selected array of other emerging economies, urbanization has become associated with major transformations of the urban built environment, often in the form of iconic architectural projects and massive mega-project developments that regularly coexist side by side with high overall levels of urban poverty and informality.

New Governance Arrangements

The move to transform urban landscapes into the incubators and showcases of innovation and development is greatest in cities where decentralized governance has limited the local state's fiscal capacities. In the search for fiscal incentives to attract the innovative classes, authorities have turned to the private sector for resources and ideas, thus increasing state willingness to support the building of global city landscapes. Reliance on local public–private partnerships for urban development is seen as enabling regional and national progress outside the typically slow moving and bureaucratic mechanisms of national-level governance, drawing strong comparisons with the introduction of Special Economic Zones, traditionally oriented toward industrial uses, in developing countries throughout the 1980s and 1990s (see Fuller and Romer, 2010).

In the neoliberal era of decentralization and state downsizing, experiments that enable free market zones to guide development usually involve both public and private sector actors, as both share incentives to generate and capture revenues. But when local states begin to ally with real estate developers around such massive urban transformations, and when they join private investors in displacing or dispossessing residents from properties or locations, they often face political opposition. While similar challenges in the 1970s placed the analytic focus on the failure of the state to keep pace with increasing urban populations, contemporary scholars, and development agencies have broadened the focus to include the failure of the market, private sector investment, and neoliberal structural adjustment policies to adequately account for the needs of the urban poor (see Davis, 2004; Beall,

2002; Harvey, 2008). Thus, to the extent that neo-liberal restructuring of urban space within the context of continued globalization produces extreme spatial fragmentation, exclusionary urban development, and local conflict, the route to global city status via transformation of urban land uses and accelerated real estate development rather than manufacturing and industrialization continues to be paved with social and political obstacles.

For this reason, much of the recent work produced by scholars and high-profile multilateral development agencies continues to highlight the many negative externalities associated with the dispossession and dramatic transformations in urban land use deployed in order to pave the way for these new projects, including decreasing access to shelter and secure tenure for existing and incoming populations of urban poor and displacement of vulnerable populations to the urban periphery. Even among those scholars whose concern is less about land use change and more about the seemingly inexorable process of urbanization that draws ever larger proportions of a nation's population into a circumscribed spatial orbit, assessments underline serious challenges. From inadequate infrastructure to environmental degradation to significant increases in urban poverty and rising rates of violence and insecurity (see Martine et al., 2008), rapidly urbanizing cities are seen as hosting a plethora of pathologies that persist in the midst of accelerating prosperity.

Urban Informality: Where Citizens, Urbanization, and Development Collide

In the most rapidly urbanizing regions of the world, the management of urban informality, most clearly manifested through the increasing occurrence of slums and informal settlement patterns, has emerged as one of the most consistent lens through which scholars and practitioners now address the costs and benefits of rapid urbanization across the developing world (Roy and AlSayyad, 2004). While the cities of Sub-Saharan Africa have the highest rates of informality and slum growth as a percentage of total urban expansion, Asian cities are now home to the largest total number slum-dwellers, placing the issue at the center of a multidisciplinary debate over the role of urban informality as a driver or inhibitor of economic development. From an economic standpoint alone, the informal economy in developing nations, operating primarily in the urban periphery and 'slum' settlements, is estimated to account for upwards of 50% of all urban employment across the developing world (see Becker, 2004). Despite the observable increases in per capita economic productivity that accompany rural–urban migration, others point out that the lack of formal tenure and property rights which has accompanied the relative lack of affordable housing provision by local governments and the private sector alike, alongside the inadequate provision of educational opportunity, likely account for tens of billions of dollars of unrealized capital in slums (see de Soto, 2001; Yamauchi et al., 2009).

Renewed interest in the forms and functionality of informal settlements is also closely related to the continued consolidation of human rights at the heart of development discourse, most clearly articulated through the formulation and adoption of the Millennium Development Goals (MDGs) as primary measures of development and progress in the twenty-first century. The demographic shift to a majority urban global population, along with the expansion of urban footprints at rates that more than doubles that of urban population growth (see Angel et al., 2011) mean that the environmental, economic, and social impact of urbanization has a progressively more meaningful impact on national and global outcomes. In this capacity, cities have emerged as one of the few truly cross-cutting arenas in which to effectively implement policies and measure progress toward meeting the MDG targets (see Hasan et al., 2005).

Beyond the Urban: Rescaling the Territorialities of Development

Though urbanization is likely to remain widely regarded as the primary source of development, employment, and capital accumulation in the decades to come, advances in data collection and analysis methods, along with renewed questioning of what spatial and demographic characteristics define the 'urban' as opposed to 'periurban' and 'rural', have led many to begin questioning the utility of these categorical indicators and whether they can truly measure relationships between urbanization and development outcomes. This is particularly true of comparative urban studies, which, more often than not, rely on census data that is markedly inconsistent internationally. Levels of urbanization in both India and China, for example, can be characterized well above or below 50% depending on the classification of 'urban' employed, posing serious questions about how to effectively utilize this data in policy formulation and planning efforts (see Satterthwaite, 2010; Zhang, 2004). The continued dissemination of information technologies has also lead many to question traditional differentiations between 'rural' and 'urban' given the fact that many populations living outside the traditional limits of cities can now earn the majority of their income via nonagricultural employment.

Moving beyond the demographic and spatial inconstancies in characterization of the 'urban', some headway is now being made in bridging the traditional, rigid differentiation between the literal and theoretical territories in which urban and 'nonurban' development articulations and trajectories play out. In her groundbreaking study of urban transformation in China, for example, You-Tien Hsing (2010) provides a strong historical case for a more holistic understanding of the development-urbanization nexus through her description of how regional, rural, and urban land-management policies and practices have combined to profoundly impact everything from human rights and land tenure, to agricultural development and ecological sustainability, to the nature of state formation and capital accumulation in modern China. Further broadening the theoretical landscape of development, the analytical framework of 'Planetary Urbanization' (Brenner and Schmid, 2011) aims to actively integrate the various spatial scales and diverse social, political, and economic feedback loops through which urbanization is transforming the human experience. It seems likely that in the coming decades those questions

emerging at center of the multidisciplinary study of development and urbanization will require increasingly dynamic understandings of the interconnected and fluid relationships between the city and its hinterlands, as well as the between regional, national, and global transformations that will accompany the continued process of urbanization.

Development Geographies

Abstract

This article outlines key strengths in development geography arguing for a plural understanding of development geographies rooted in different traditions, schools of thought and generated by place and history-specific interests and diverse policy and interdisciplinary forms of engagement. It highlights development geographies' contribution to debates on participatory methods and argues that current research funding regimes are likely negatively to affect how development research knowledges are being produced. This article outlines three productive interfaces within geography around postcolonial, urban, and political agendas in development which are helping to make sense of the rapidly changing global contexts of development and inequality.

What is Development Geography?

Development geography produces debate and analysis on international development and global inequality. The hallmark of work in this area is the elaboration of theory from sustained field engagement in specific Global South settings. Because of this it makes an important contribution to the wider discipline of Human Geography and other social sciences by emphasizing the need to bridge North–South divides and international distances in knowledge production about geographical themes. It is a well-established research subfield and a very popular part of the undergraduate curricula. Geography departments often house introductory courses for students from other disciplines as part of foundation training.

Like scholars working in the policy-focused discipline of Development Studies, many development geographers produce "issue-driven research concerning the analysis of global to local processes of cultural, demographic, economic, environmental, political, technological and social change in developing and emerging parts of the world." (Definition of Development Studies research taken from the Anthropology and Development Study Research Excellence Framework of the UK Higher Education Funding Council. www.ref.ac.uk/media/ref/content/pub/.../01_12.doc (accessed 13.08.13.).) They also make a distinct contribution to Development Studies with the introduction of concepts such as scale, connectivity, political ecology, socionatures, and postcoloniality, as I elaborate below. Many individual scholars also engage with specific Area Studies audiences, participating in international learned societies (e.g., Latin American Studies Association, African Studies Association, Association of South East Asian Studies) and publishing in their journals. The International Geographical Union (http://www.igu-online.org/site/) also provides an important global network for geographers that cuts across North–South–East–West. The presence of feminist scholars, in particular, in this network has shaped gender and development research since the publication of the first edited collection by geographers (Momsen and Townsend, 1987). The presence of development geography has also been institutionalized within the two largest national-based learned societies: the Developing Areas Research Group of The Royal Geographical Society with the Institute of British Geographers and the Development Geographies Specialty Group of the Association of American Geographers. While development geography is published in journals associated with these learned societies, the Singapore Journal of Tropics Geography, founded in 1953, represents a longer tradition of publishing research dedicated to the 'tropical world.' While the term 'tropical geography' is an 'amorphous' category associated with colonial geographical imaginaries (Savage and Sidaway, 2008: 236), the more generic label 'development geography' also comes with intellectual and political baggage which shapes how it is defined and received by wider academic communities. Linked to geography's own history as a discipline, which emerged from British colonial interests in 'distant' places and people, this complex story has shaped how development geography is seen by different audiences and in part explains its often ambivalent position as a subdiscipline in wider intellectual, institutional, and policy landscapes.

As the world changes and new global processes and power reconfigurations emerge, this history and context continues to provoke questions about what development is and whose development geography we are talking about. Below I outline some of the main strengths of development geography arguing for a plural understanding of development geographies rooted in different traditions, schools of thought and generated by place and history-specific interests. I point to the role that interdisciplinarity and a long track record in conducting engaged research have played in forging diverse development geographies. In the section on methodologies I highlight development geographies' contribution to debates on participatory methods and suggest some potential threats that current research funding regimes present for the ways in which development research knowledge is being produced. I end by highlighting three productive interfaces within geography around postcolonial, urban, and political agendas in development which are helping to make sense of the rapidly changing global contexts of development and inequality.

Development Geographies

Treated with caution because of geography's colonial origins and characterized in the past, by some, for producing

a theoretical case study research, development geography has undergone a transformation over the last decade. It is now recognized as an intellectual home for fruitful cross-discipline collaborations that responds to the diverse nature of contemporary development challenges. As a result, current work is shaping development debates on the 'big issues' such as climate change (Pelling et al., 2001), poverty (Rigg et al., 2009), and the changing world order (e.g., Mawdsley, 2012). In this context different 'development geographies' are emerging to capture the breadth of this field both in terms of epistemological and methodological approaches as well as thematic and empirical focus. Existing strengths in development geography are being deepened and new research directions are emerging encompassing geographers across all geography subdisciplines including economic geography (see Peck and Sheppard, 2010). Academics based in Development Studies, Planning and Sociology increasingly publish on development topics in Geography journals, while a Scopus search indicates that articles by geographers ranked in the top 50 downloaded papers in leading Development Studies journals for the period 2006–12 (see **Table 1**). Papers by geographers ranked first and second place in World Development (Blaikie, 2006; Rigg, 2006). Together with Bebbington (1999) these papers appear in the list of top 25 downloads in World Development over the last decade.

Calls for more critical thinking about what precisely is meant by 'development geography' as opposed to 'geography in developing countries' (Simon, 2011) have been at the heart of moving geography and wider social science debates away from thinking about the Global South/North as separate. From the 1990s onwards this agenda harmonized particularly well with the growing interest in globalization. As a result, a strong body of research emerged around globalization-related themes of transnationalism and mobility that built on long-established interests in the connections between places. In particular research has examined the development implications of boundaries becoming more fluid with globalization and the repercussions of increased mobility for how development is understood and practiced. Attention has been drawn to the limits of crisis-driven narratives in the 'age of migration' (Silvey, 2009: 508) to focus more positively on the role of circular migrants (Potts, 2010) and diasporas (Mercer et al., 2008; McIlwaine, 2011) in brokering and imagining development in specific ways that emphasize the myriad social, cultural, and economic connections between places across distance. This includes work on migration as a form of adaptation to climate change (Black et al., 2011) while related research points to how Information and Communications Technologies (ICTs) for development (ICT4D) are potentially able to bridge digital divides and promote sustainable development (Kleine and Unwin, 2009).

Geographical research on globalization has also been characterized by interrogating the relationship between globalization and neoliberalism thereby providing a robust critique of the global power relations of development. As a result, research on structural adjustment and its key characteristic elements (privatization and the switch to export commodity production) is a hallmark of much development geography. Particularly strong scholarship has emerged on Latin America and the Caribbean (Kohl, 2004; Perrault and Martin, 2005; Klak, 1998). Critical attention has also been paid to the rise of neoliberal ideas about how to 'manage' development with research focusing on the growing audit culture, professionalization processes as well as scrutiny of the means through which such ideas travel and become consolidated globally (Townsend et al., 2004; Larner and Laurie, 2010).

Work on neoliberal natures is also currently shaping agendas in development geography building on a rich body of work in political ecology, one of the most significant contributions to development research more generally in the last few decades. Bill Adams' land mark Green Development (2008) is in its third edition, Peet and Watts' (2004) highly influential Liberation Ecologies is in its second, and the foundational of work of Piers Blaikie has been profiled in journal special issues (e.g., Geoforum ('In honor of the Life Work of Piers Blaikie' Special Issue in Geoforum 39:2, March 2008. with nine articles including 'Epilogue: Toward a future for political ecology that works' (765–772) by Piers Blaikie)). Research in this area brings livelihoods together with political ecology in a way that helps rethink rural development in Asia (Rigg, 2006), Africa and Latin America (Bassett and Zimmerer, 2003) and provides new frameworks for thinking about natural resources (Watts, 2004). Indicating the reach of this work in geography more widely, the first two annual keynotes of the Cultural and Political Ecology Specialty Group at the annual conference of the Association of American Geographers were given by Tony Bebbington and Piers Blaikie in 2010 and 2011.

Engagement, Influence, and 'Impact'

The nonacademic influence of development geography research has changed policy making, development practice, and debate. Landmark books on Political Ecology (see above) and Participatory Development (see below), for example, have changed the way in which development issues are imagined and tackled, influencing nonacademic development stakeholders at all scales. Illustrating strengths in political ecology, urban research, and gender and development, examples of recent high-level engagements by development geographers include working with different United Nations agencies. Development geographers have authored and acted as commissioning editors for a number of recent UN HABITAT 'state of the world' reports (e.g., UNHABITAT, 2010 (*State of African Cities 2010* Professor David Simon, Royal Holloway, University of London State of); UNHABITAT, 2012 (*Women in Cities: Gender and the Prosperity of Cities 2012–13* Professor Sylvia Chant, London School of Economics)); Moser and McIlwaine's (2006) work on gender and violence has shaped the World Bank thinking by providing a typology of economic, social, and political violence perpetrated at different scales – individual, community, city etc.; Bebbington's work on civil society has also been very influential in wider international donor policy circles, especially in terms of highlighting the relationships between different types of civil society organizations and the state. A joint publication with World Bank colleagues on this work (Bebbington and Dharmawan et al., 2006) is one of the top downloaded articles over the last decade in world development.

Influence on bilateral donor organizations has also been achieved in a number of ways with geographers contributing to 'national flagship' areas of international development expertise. In Europe for example this includes the Norwegian Agency for Development Co-operation's profile in post conflict humanitarianism and development and Denmark's Development Organization's expertise in youth and development. (Drawing on the work of scholars such as Professor Kristian Stokke (accessed 13.08.13.) http://www.sv.uio.no/iss/english/people/aca/stokke/and Professor Kate Gough: http://www.lboro.ac.uk/departments/geography/staff/gough-k.html (accessed 13.08.13).) In the UK the Department for International Development's (DfiD) sustainable livelihoods framework draws on the political ecology research of Blaikie and others which linked concepts of vulnerability and risk to natural disasters and rural poverty (Wisner et al., 1994). Stuart Corbridge et al.'s work on India (2005) also influenced the UK government thinking on state formation through engagement with the Crisis States Group at DfID. While these examples illustrate how individuals have shaped policy through advisory roles and research dissemination, specific funding streams have also been created in recent years to enhance the academic–policy interface. The UK's 'ESRC-DfiD joint fund for poverty alleviation research' scheme launched in 2009 is an emblematic case through which a number of geography-based projects have been funded. (For more details of the ways in which UK development geographers have engaged with development donors and stakeholders see the review of UK development geography for the ESRC-AHRC international benchmarking review of Human Geography: http://www.rgs.org/OurWork/Research+and+Higher+Education/International+benchmarking+review+of+UK+human+geography.htm.)

While engagement with large donor organizations produces policy-focused development geographies that speak to the global development industry, diverse development geographies are also produced through research engagement with a plethora of grassroots organizations and NGOs operating in the Global South. This engagement often brings direct benefit to some of the poorest members of society. For example, Tony Bebbington's research on mining has been credited by the Peru Support Group for ensuring a UK company paid compensation to farmers for human rights violations. Dorothea Kelin's research on Fair Tracing (www.fairtracing.org), which used smartphones to give consumers more traceability information, persuaded the UK's leading ethical consumer magazine to move their online ethiscore subscription service for shoppers to online phones. This type of impact emerges from a politics of knowledge production that aims to be about working 'with' and not 'on' the Global South. A wide range of innovative forms of working, partnership, participatory practices, and coproduction with local organizations underpins such an approach to research, as we discuss in more detail below. Nevertheless it is important to recognize that the term 'impact' itself is controversial, for its implied unilinear, one-way effect which often makes invisible the coproduction of development knowledges and privileges development outcomes that can only be measured in restricted ways. The recent rollout of an impact agenda by research funding bodies in many settings continues to generate debate among development geographers (Williams, 2012).

Methodology: Participation, Collaboration, and Coproduction

The book *Participation: the New Tyranny* (Cooke and Kothari, 2001) and its follow-on companion text *Beyond Participation: Strategies for Deeper Empowerment* (Mohan, 2004) shifted how participation issues are framed and taught in contemporary

development theory and practice globally. This discussion developed in part from the valuable cross-over between Geography and Development Studies outlined above and from strengths in reflexive methodological research practice in development geography. (Both Professor Uma Kothari and Professor Giles Mohan are geographers based in Development Studies Units in the UK.) This background served as a springboard for both books' critique of the ways in which participation has entered development planning and practice, often reflecting 'tick box' approaches that are more akin to consultation with 'aid recipients' rather than genuine participatory engagement with grassroots development actors around empowerment agendas.

Feminist development geographers, in particular, have been long-time champions of grassroots empowerment and participatory approaches in development geography, resulting in the coproduction of knowledge with marginalized groups and Global South NGOs in many cases. Laurie et al.'s (forthcoming) work with an NGO founded by trafficked women in Nepal (www.shaktisamuha.org.np (accessed 13.08.13.)) provides a recent example of such an approach (see http://www.posttraffickingnepal.co.uk/ (accessed 13.08.13.)). For feminist development geographers based in North America the coproduction of knowledge with Global South feminist activists has often been facilitated by strong links between Geography and Women's Studies. Examples include research with the women's organization 'Red Thread' (https://www.facebook.com/RedThreadWomenGuyana/info (accessed 13.08.13.)) in Guyana (Peake and Trotz, 1999) and the work of the Sangtin Writers with Richa Nagar (2006) focusing on feminist thought and activism in India. These sets of works are based on long-term working partnerships and collaborations with specific NGOs and a commitment to a feminist politics of knowledge production. In these ways feminist geography makes important contributions to development debates on empowerment through collaborations with Global South partners including in non-English-speaking environments. The feminist geography journal *Gender Place and Culture*, which publishes much development geography, was a pioneer among geography journals in introducing multilanguage abstracts, indicating a commitment to making research more accessible internationally. Feminist-engaged research on development also influences international policy making through strategic collaboration with specific international donors resulting in the sorts of coproduced policy outputs on gender and violence identified in the previous section.

While there is much to praise in development geography's emphasis on participatory methods and the coproduction of knowledge through collaborations that cross North–South, current shifts in research funding represent a number of threats to the ways in which development geographies are produced. This includes the ways in which full economic cost models potentially undermine strengths in ethnographic research and the fact that low academic wages in Global South universities generate consultancy driven systems which provide little time and space for academics to reflect on their field experiences. While it is argued that ICT4D offer opportunities to bridge the digital divide, scholars and activists based in the Global South continue to face structural biases and inequalities in terms of publishing in international peer-reviewed journals and in accessing journals generally, whether online or in hard copy. It remains unclear the extent to which current debates about open-access publishing protocols will resolve or deepen these problems. Together with the increasing costs of postgraduate fees, especially for international students and the poor funding for thesis completion at undergraduate and postgraduate levels in many countries in the Global South, these factors mean that the capacity to build long-term, engaged research collaboration across difference and distance is diminishing.

New Development Actors and Emerging Academic 'Interfaces'

Contemporary changes in the economic world order are demanding new conceptual tools for understanding development. While development geography has traditionally focused on grassroots organizations, NGOs, the state, international agencies and, to a lesser extent, religious organizations, research has recently shifted to embrace a range of emerging development actors and processes. These include for example, BRIC economies as donors and investors (Mawdsley, 2012) as well as children and youth (Jones, 2011) and indigenous people (Andolina et al., 2009) as authors of 'alternative' development logics. Social justice movements (Cumbers et al., 2008), international volunteers (Baillie Smith and Laurie, 2011), celebrities (Brockington, 2009), and ethical consumers (Goodman, 2010) have also become new research subjects. A growing body of work examines how they act as development brokers and interpreters when they engage with and performing diverse forms of global citizenship.

Much of this work on new actors has been inspired by the lead that development geography has taken in theorizing postcolonialism in relation to different aspects of development (Power et al., 2006). Research has examined postcolonial development at its interfaces with culture (McEwan, 2001), economy (Pollard et al., 2009), and (geo)politics (Noxolo, 2006). In this way innovative research has interrogated identity making and the performative construction of (diverse) economies, politics, and knowledges including ethical, alternative, and fair trade. As a result, development geography has forged new agendas and innovative interfaces with urban and political geographies that have sought to 'provincialize' (Chakrabarty, 2000) the so-called metropolitan thinking.

For urban geographers writing of and from contexts like South Africa, where the analyses of urban space has led to compelling arguments to reformulate the Global South as comprising 'Ordinary Cities' (Robinson, 2006), the relevance of development labeling is something to call into question. Raising such questions, however, can provoke strong reactions, as Sue Parnell makes clear in some personal reflections on her forthcoming book (Parnell and Oldfield, 2014). Here she argues that the current global context, in which neoliberal policies are affecting cities globally, requires a rethinking of urban theory:

> I have spent much of the past 7 months presenting talks on (re) theorizing cities from the Global South in intellectual centers of the Global North - London, Geneva, New York, Paris, Manchester and Edinburgh. I have been surprised at the often intense emotional

reaction that the suggestion, premised on the facts of the global reconfiguration of population and economy (to urban Africa, Latin America and Asia) and the distortion of academic knowledge production, that there is an imperative for theoretical and empirical recalibration in urban studies.

In its crudest form the push back or negation of the call for a more Southern urban studies is an objection to the suggestion that work undertaken in Europe or North America is no longer cutting edge or universally relevant. There is also an austerity tinged objection, based on the erroneous conflation of the term 'the Global South' with that of poverty and exclusion, that objects to the suggestion that cities in the Global North have no serious problems and that inequality and deprivation are the preserve of the South.

Speaking at a panel session 'Theorising from the global South: Inverting and challenging geographies of knowledge production,' RGS-IBG annual conference, Edinburgh, July 3–5, 2012, session organized by Charlotte Lemanski and Katherine V. Gough.

Her interpretations of what the reactions to her analysis imply about geographical imaginaries of development, poverty, and knowledge production are important. At another level, the response that her call for new ways of thinking has provoked can also been seen as indicative of how changing global circumstances are generating ontological insecurities within the discipline. The realignment of global power and changing economic and political configurations are pushing geographers to rethink their geographical maps (Sidaway, 2012) and to reexamine 'the politics – personal and professional' of "parachuting into new and unfamiliar terrain armed with little understanding of the specificities of 'other' places and with only Western theoretical toolkits" (Pollard et al., 2009: 138). In development geography these types of anxieties have led to a reevaluation of the contribution of empirically rich, historically grounded ethnographic analyses of development (Silvey and Rankin, 2012) inspired by postcolonial approaches which aim to speak across North–South (McFarlane, 2006) and disciplinary differences (Rankin, 2003).

Conclusion

Development geography has transformed itself over the last decade. Responding to calls for more critical thinking about what development is and means in the contemporary world, it is providing an important analysis of the key challenges the world is currently facing. It is also making visible the geographies and politics of knowledge production that shape why we see these challenges in particular ways.

What constitutes development geographies and their relevance to wider debates about international development and global inequality depend very much on where a researcher is looking from: what their engagement is with that place, its connections, its people, different schools of thought, and their own biographies (academic/activist/personal). It is only possible to understand the ambivalence and sometimes tension around the use of specific ideas and labels, if these factors are taken into account and given critical consideration. Unequal power relations mean that exclusions, namings, and silences play an important role in knowledge production around development. These factors influence which academics, from where, become labeled as what, and listened to by whom. Development geographers aim to make these issues visible in their work. In this way they help ensure that important questions about whose development geography continue to be forefront in analyses of global inequality.

Development: Organizational

Abstract

Organizational Development (OD) is a field of applied social sciences devoted to understanding and facilitating change processes in organizations. Techniques to overcome resistance to change and methods for managing the renewal process in organizations effectively are at the very core of this discipline. While OD interventions address various organizational levels (individual, group, department, organization), they usually aim at changing the target system on both dimensions: structure and behavior. Various OD programs have been developed, among them the most salient are Survey–Feedback and Process Consultation. OD has been criticized for ignoring the power relations in organizations, for misreading resistance to change behavior, and for misconceiving change processes as exceptional episodes. More recent approaches reconceptualize change as a continuous feature in organizational life, thereby exaggerating the fluidity of social institutions. Concluding remarks advocate a view of mastering the delicate balancing of stability requirements and change challenges.

Historical Overview

In classical organization theory, the problem of coping with organizational change was not of much concern. Change basically meant reorganization and the critical activity was to develop the best organizational solution for mastering new situations brought about by diversification, mergers and acquisitions, internationalization, factory closure, etc. Implementing the new design, if regarded as a problem at all, was conceived as a problem of careful preparation and of giving the right instructions. After a brief period of tolerance, all employees were supposed to work according to the new organizational guidelines.

This traditional model, however, rarely proved to be a success: organizational members notoriously resisted the new organizational design, unforeseen events rendered the new design worthless, or the change process came to nothing.

The typical reaction to these irritations was to blame the plans for having been imperfect and to push harder for renewal. In most cases this reaction pattern actually made the situation even worse; the resistance became stronger, the rejections more sophisticated, etc. Although the problems of organizational change made themselves strongly felt in practice, for a long time they did not gain the status of a critical issue in classical theory.

It was the behavioral sciences, especially the Human Resources Approach, that put organizational change on the research agenda and developed approaches for understanding the texture of change processes.

The impetus to establish organizational change as a special research field came from empirical studies finding that success in change critically depends on the attitudes of organizational members as well as on the general mood toward the new design. This insight was provided by studies on 'resistance to change' (Lawrence, 1954).

Studying resistance to change, as well as approaches on how to overcome it, dates back to Lewin's (1958) experiments. Most salient are his seminal experiments on changing deep-seated food aversions and avoidance. Group meetings and active involvement of group members proved to be the best way to change food habits. The foundations for what were later to become the 'golden rules' of successful organizational change have been laid in these studies:

1. Broad information at an early stage and active participation in the change process.
2. The group as an important medium (facilitator) for change: change processes are perceived as less worrying in groups and generally are accepted more easily.
3. Mutual cooperation among organizational members.
4. A settling-down period at the end of the change process designed to institutionalize the changes that were carried out.

Lewin (1958, p. 210) later elaborated on these insights and conceived the well-known 'triadic episode' of successful change. The model builds on the idea of homeostasis and advocates a three-stage process: unfreezing, moving, and refreezing (see Figure 1).

The most important insight of this model is that organizations need an initial period of irritation and relaxation to enable them breaking up their habits and routines. Or as Lewin put it, organizations have to undergo a stage of 'unfreezing'; otherwise, they are not likely to leave their equilibrium position and to move to a new level. Changes tend to be short lived if there are no efforts to bring them to permanency. The new patterns, therefore, need 'refreezing'; that is, the system has to settle down again and find a new equilibrium.

Organizational Development as a Discipline

Lewin's group experiments and his three-stage model brought about a totally new form of behavioral training (Laboratory Method) designed to cope with habits and changes. This new technology of group intervention and feedback soon became very popular and built the core of the newly founded National Training Laboratories in Group Development. A series of further related approaches emerged. As a result, facilitating and supporting organizational change processes increasingly became a management consulting profession. All these studies and initiatives eventually gave rise to establishing a new field, special discipline within behavioral sciences, called Organizational Development (OD).

Figure 1 Lewin's triadic episode of organizational change.

Among the other theoretical and practical streams of OD, the 'Survey–Feedback' approach features prominently. This approach makes use of attitude surveys and data feedback to organizational members as a means of facilitating change processes (Bowers and Franklin, 1976). All organizational members are invited to take part in the change process including data collection and analysis as well the design of change initiatives (shared power approach). The intention is to stimulate organizational members' interest in change and to create a motivation for overcoming the current state and its weaknesses. The general aim is to initiate a joint problem-solving process. Research on the effectiveness of Survey–Feedback intervention found that the greater the involvement of organizational members in the survey process, the greater was the awareness of problems in the organization.

Another closely related OD building stream was the work of The Tavistock Institute (UK) which is deeply rooted in psychotherapy and group therapy (Bion, 1961). Tavistock started to transfer clinical methods to organizational change settings in the early 1950s. The doctor–patient interaction pattern and the corresponding high professional demands put on the change agents stand for this conception. Among the different methods used in this context the so-called Tavistock Conferences feature prominently. These are leaderless group discussions designed to experience and to explore leadership, authority, and obedience.

A further impetus in building OD came from approaches to redesign jobs and to the improvement of the quality of working life. Here again, The Tavistock Institute (of Human Relations) played a major role by conducing the sociotechnical systems approach. That is, a conceptual framework and an action research program which is devoted to meet both individual needs and technical demands (Rice, 1958). The emphasis is on changing traditional Tayloristic organizational design toward group-oriented work designs providing organizational members more variety, meaning, and feedback in their work.

Later, the scope of OD and the repertoire of OD interventions were extended significantly. Among them the conceptions of organizational learning, corporate culture, and sensemaking play a major role. Also, OD has been linked to strategic management and strategy renewal. All the additional approaches and new issues considerably enriched the field but made it at the same time more diverse. At the core of OD, however, there still remain theories of change and interventions devoted to effectuate change at different levels of social systems.

OD: Conception

OD is truly interdisciplinary in both focus and methods. Even though different perspectives exist on what OD is and should be, some overarching characteristics can nevertheless be identified (Cummings and Worley, 2008):

1. *Holistic:* OD is a holistic approach; it seeks to change both structure and behavior. While OD aims at changing the entire system, the interventions address different levels: individual, group, intergroup relations, department, division, and interorganizational relations.
2. *Planned organizational change:* OD conceives organizational change as a planned, systematic activity building on a longer-term perspective.
3. *Based on social sciences:* OD methods and procedures apply knowledge from social science research; it is explicitly science based.
4. *Full cycle:* OD defines change as a project and aims at including all stages of a change project: its initiation (unfreezing), its realization (moving), and the subsequent stabilization (refreezing).
5. *Change agent:* OD projects are conducted by external professional consultants who are trained in applying sophisticated intervention techniques and clinical methods. Organizations are assumed to often misread critical signals and to stick closely to their traditional mind-sets which easily amount to invisible barriers to change. They therefore need professional help from outside for reanalyzing the problems at stake and redefining the setting in innovative ways (reframing).
6. *Top management support:* Commitment of the top management group is considered a precondition of any successful OD project. A commitment is expected in both paying attention to the change problems and giving the OD intervention a sense of urgency.
7. *Shared power approach:* OD processes are designed to involve all parties affected by the change project and to encourage participants to jointly develop new solutions. Authority is still present but there is a willingness to share power. Organizational members have a voice in the process and are expected to become committed to the change project. They share their knowledge.
8. *Integration:* OD projects aim at integrating the individual and the organization by reaching both organizational effectiveness and fulfillment of individual needs.

From time to time, new themes were additionally included. The inclusion of these parts did, however, not result in a paradigm shift or an essential theoretical revision. Up to now, the overall framework has basically remained the same.

OD Models

Various authors and consultants have developed comprehensive OD programs; among them four models are salient: (1) Survey-guided Development, (2) Process Consultation, (3) Grid Organization Development, and (4) Systemic Intervention.

The Survey-Guided Development

This model is based on a multistep data feedback procedure. After an orientation stage a survey is conducted using a standardized questionnaire to gain a comprehensive diagnosis of the client organization's situation, its major problems, and

their possible causes. The diagnosis is based on a theoretical model of organizational functioning as a frame of reference (Likert, 1967). The emphasis is on gaining a solid and rigorous database, which allows for developing systematically further activities. Starting points are discrepancies between the model of organizational functioning and the observed and measured status quo (the conception comes close to a classical medical treatment). The subsequent data feedback is a further cornerstone of this model. All organizational levels are involved. It is essential that the persons involved understand the data and the underlying problem diagnosis. Feedback is typically provided in the context of the work groups. Supervisors are assigned an important role in the feedback process. Apart from process facilitating change agents are primarily conceived as knowledge brokers, they should link theoretical knowledge and the world of action. The aim of the feedback sessions is to determine what changes seem to be required, how they should be reached, and what interventions are appropriate. In general the data feedback aims at unfreezing participants' perception patterns and encouraging their willingness to take part in the change process. Follow-up surveys serve to monitor the progress of the OD process and to determine whether the change efforts did work. A somewhat similar abbreviated form of this model is the *Confrontation Meeting* originally developed by Beckhard (1967). Data collection and evaluation are conducted directly and in a condensed form (1 day only). A meeting of all those organizational members involved is held to identify the major problems of the system. After a joint ranking of the problems, the unit develops an action plan and establishes a system of periodical reports on the progress of implementation.

Process Consultation

This is a nondirective model for supporting the client organization in carrying out change processes; it was originally developed by Schein (1988). The process consultant helps the client organization to figure out what should be done to improve the situation. A Process Consultation project typically includes the following stages: entering and defining the relationship, choice of setting and work methods, data gathering, clarifying and confronting interventions (e.g., through the use of feedback or coaching) by the consultant, evaluation of results, and consultant's disengagement. Due to its indirect character, the results of Process Consultation are not predictable at the beginning. Opposed to the Survey-guided Development model, Process Consultation does not rely on a specific theory of organizational functioning as a basis for identifying problems and formulating solutions. The consultant is expected to 'go with the flow' and to realize that the client organization is the 'owner' of the problem and in charge for finding a solution. The consultant is conceived as enabler and not as problem solver.

Grid Organization Development

This is a highly standardized intervention program building on one basic conception; that is, an ideal managerial style with high concern for both people and productivity (Blake and Mouton, 1969). The development process is designed to unfold along six distinct phases: Grid Seminar, teamwork development, intergroup development, developing an ideal model for the whole organization, implementing the model, and examination of the organization's progress toward the plan.

Systemic Interventions

This is a more recent OD model that builds on family therapy and systems theory. The major focus is on fixed paradoxical interaction patterns as invisible barriers to organizational change, thereby drawing on the Double Bind Theory of Schizophrenia (Watzlawick et al., 1967). The transformation of these ideas into an OD approach originally was initiated by the Italian family therapist Selvini-Palazzoli (1995) and her Milan School. In a first step this approach aims at surfacing hidden rules and games in organizations. These patterns (among management teams, between groups, etc.) are assumed as being possibly vicious in character; their circular reinforcement is likely to consume a lot of the system's energy and to evoke strong aversions against any attempt to change them. Due to the circular involvement of the organizational members, this approach refrains from participative change designs. Rather, it addresses the deeply embedded hidden agenda and its paradoxical architecture. After having identified the self-reinforcing logic of fixing the paradoxical dynamics consultants set out to dissolve it (Kilmann, 1988). OD interventions target the core dynamics of the vicious circle; they are carefully planned in terms of a counter paradox. Typical paradoxical interventions are prescription of the circumstances which are causing the symptom, positive connotation of the symptom (e.g., resistance to change), increasing intensity of reinforcement, etc. Systemic Interventions, if well targeted, are likely to result in 'explosions'; that is, the whole architecture of pathological rules collapses like a house of cards, thereby stopping the fatal circles of recursion and paving the way for reopening the system. The general aim is to regain the scope for necessary change. The form of the resulting transformation is, however, hard to predict; new patterns emerge and get reinforced. The result of the process is, however, not fully under the control of the actors.

OD and Beyond

In the beginning the OD approach was received enthusiastically in both theoretical and practical fields but later became increasingly criticized. The most common objection is to the underlying premise of harmony of interests; that is, promising OD projects meet always both employee needs and the organization's efficiency goals. Critics doubt whether there is always such a win–win solution for interest conflicts when responding to change requirements (under fierce competition). This argument leads into a broader criticism accusing OD of showing a general naïveté toward organizational power structures. It is said that OD actors can never claim neutrality because they always operate within power structures and are therefore likely to become part of micropolitics. Also, the financial compensation of the change agents is emphasized. It does not allow them to play the alleged neutral role in the change process. Instead of sharing power OD is criticized of increasing the power of management.

Another objection relates OD to hidden agendas. It is suspected that OD consultants often provide legitimation for a predetermined change program. Management wants them to

skillfully confirm and realize what they have already fixed (Zand, 2010). Agreement is reached through a process design which actually does not leave any scope for members' influence.

In addition to these objections a lack of solid theoretical foundation has been diagnosed. The focus is on techniques and instruments but there is no compelling overarching conceptual framework.

Recently, a new debate on the nature of change came into the foreground of academic and practical interest (Brown and Eisenhardt, 1997). It goes beyond the criticisms mentioned above and fundamentally challenges the paradigm of organizational change underlying OD models. The focus is on the conceptualization of change; episodic change is contrasted with continuous change (Weick and Quinn, 1999). OD clearly stands for episodic change.

Episodic Change

An in-depth analysis of the OD approach reveals three assumptions on the nature of change.

Organizational Change is a Clear-Cut Process

In OD and related approaches, organizational changes are conceived as clear-cut processes with a clearly defined beginning and end, processes that are separated from ordinary organizational operations. This view misconceives the character of organizational processes. Problem-solving processes largely overlap in terms of participants, subjects, and interests and penetrate each other (March and Olsen, 1976). This results from the fact that organizations are, after all, to be managed in a complex and ambiguous context. Change processes are an integral part of the system's general dynamics; they are not separate entities or islands. The definition of a change period is always an artificial construction within a flow of events. The system observes the OD activities and reacts to them, thereby involving the project into the everyday dynamics.

Organizational Change is an Exception in Organizational Life

In OD change is given a special status, that of an exception. It is conceived as an extraordinary phase, which tends to be infrequent. Organizational members perceive them threatening and somewhat chaotic. In this view, changes come close to disturbances likely to confuse the rational order and system of rules. The guiding idea is the stable state of equilibrium. Stability stands for efficiency, rationality, and harmony. Organizational members are assumed to be strongly in favor of order and stability and to feel helpless and frightened when facing change requirements. Furthermore, change is conceived as replacement: Model A does no longer work and therefore has to be replaced by a new model. The replacement thinking favors an either-or logic which (implicitly) excludes multidimensional views of problems and solutions (Weick and Quinn, 1999).

Organizational Change is an Area for Specialists Only

The strong psychological or even psychotherapeutic orientation of OD led to the implicit assumption that organizational change should be restricted to specially trained professionals only. The organization or department is put into the role of a client or even a patient who badly needs a 'doctor' to master the challenge 'illness' of change.

This perspective puts managers into a paradoxical situation. They are expected to rationalize and improve procedures and structures, but the important function of putting improved systems into action is said to be an exercise of which they are not capable. This corresponds with the episodic view, the rare event logic. But can such view match the actual situation in modern organizations where change has become such a prominent feature? The recent debate brought a counter paradigm to the fore: the image of continuous change. Modern organizations are reconceived as *inherently restless* and fluid in nature.

Continuous Change

The alternative view portrays change processes in different terms, the emphasis is on ongoing processes, emerging and located in everyday practices. They unfold simultaneously across units and levels and may eventually accumulate to a far-reaching reorientation of the system. Some models to portray the reverse logic have been developed.

Weick (1977), for example, discusses a radically contrasting model, the 'chronically unfrozen' organization. This refers to an organization that has the unfreezing stage as the rule and refrains from any refreezing. More recent organizational concepts follow the same line of reasoning by emphasizing continuous processes of coming into being, adaptations, modifications in organizational practicing and relentlessly changing forms of cooperation (Orlikowski, 2002).

Other authors (e.g., Brown and Eisenhardt, 1997) conclude from their empirical studies that the ability to change continuously has become a critical success factor and the basis for competitive advantage. These studies show that for many firms relentless continuous change is at the heart of their character, nothing but 'business as usual.' They are constantly redesigning their practices. There are striking similarities with the entrepreneurial discussion in economics. In particular, it is reminiscent of Schumpeter's notion of permanent 'creative destruction' as a critical element of any efficient market economy. In his view, the basic role of entrepreneurs is to constantly irritate the market, so that it can therefore hardly settle down.

More recently, the focus has shifted from structural flexibility to behavioral features, such as absorptive capacity and competencies. In this context, the notion of *dynamic capabilities* features most prominently, stressing the role of organizational capacities for relentless change (Helfat et al., 2007). The idea is that organizational capabilities themselves have to become fluid to enable organizations to continuously create new (combinations of) resources. As a result, organizations are in a continuously unstable state. Dynamic capabilities are seen as a means as well as an outcome of ever-changing decision-making processes concerning resource reconfiguration, integration, and acquisition.

While these models differ on many dimensions, they all have a common core, that is, the critical emphasis on fluidity.

The ideal of equilibrium is replaced by a new ideal, the state of restless change. High-performing organizations are seen as constantly redesigning and reinventing themselves, with increasingly fuzzy and eventually dissipating boundaries. The distinguishing characteristic of these types of organizations is that their activities are no longer bound to a 'deep structure' and organizational routines built in the past. Rather, the organization is steadily revising its cognitions and changing its expectations. Departmentalization, routines, and replicable practices are seen as features representing solutions to old problems, developed for an older industrial environment which valued stability, bureaucracy, and formality as a source of building competitive advantages.

Outlook

At first glance convincing but the model of continuous change is troubled by several drawbacks as well. Put bluntly, the fluidity model radicalizes the right insight at the wrong point: change models should refrain from throwing the baby out with the bathwater. One should not forget that social systems basically need sensemaking and cognitive patterns in order to come to terms with their complex environment. Organizational practices, routines, and capabilities provide a set of problem-solving patterns that enable the system to master tasks in a complex environment and to draw a boundary. Organizations are simply not conceivable without workable identities and boundaries which distinguish them from their environment. By implication, the concept of fluid and relentlessly changing systems ignores an essential feature of any system building. The ideal of fluidity advocates the logic of reacting to any environmental event in a new (not patterned) way. As modern systems theory has clearly shown (Luhmann, 1995), organizations cannot exist and act without guidance from an organizational frame of reference, informed by past learning and experience. Reacting in a turbulent environment to any new event by improvisation and without any pattern implies giving up the distinction between system and environment (Schreyögg and Sydow, 2010).

For further advancing OD is therefore an approach needed which on the one hand avoids a too episodic view of change, and a blurring conception of fluid systems on the other hand. A new approach would have to balance the contradictory functions of flexibility and efficient replication. Change requirements can only be properly understood when put in the context of the interplay between these contradicting functions. When considering change initiatives one should not forget that organizations always also have the option to stay with the established rules, interpretation patterns, and boundaries built in the past. The system has to learn not only to adapt its practices and patterns but also to make use of intentional nonadaptation. Organizations are not relentlessly changing systems; they are partially invariant systems in a complex and dynamic environment.

While the basic OD concept of change seems to be questionable, it is not necessary to give up all those well-developed OD methods and experiences. OD methods can be reframed. The mission of OD could be reformulated to help identify communication disturbances and to eliminate learning blockades (Argyris, 1985).

Abstract

Anthropology and development as institutional practices share a common origin in the unequal power relations among peoples that shaped the modern world. Humanitarian and reformist impulses existed from the discipline's earliest days regarding the societies that served as its focus of study. Colonial administrations provided the initial setting for applied anthropology concerned with social betterment. International development was launched after World War II, prioritizing economic growth, with quality of life, equity, and sustainability later emphasized as well. Neoliberal policies and globalization once again stress growth. The rise of China, India, and other newly industrializing countries is challenging conventional views of a Western-dominated world.

Antecedents

Anthropology seeks to understand humanity past and present, including our biological and sociocultural dimensions, in a holistic and comparative manner. As a field of study, it draws on the perspectives and approaches of both science and the humanities. Social and political issues also shaped the discipline from its earliest day. The global expansion of states and markets served as the context for the profession's emergence. While its early practitioners were attracted by scholarly questions, some addressed the predicament of the societies who furnished the focal point of their investigations. Dispossession and depopulation were occurring along the world's colonial frontiers. Lewis Henry Morgan (1851, p. ix) wrote a pioneering ethnography on the Iroquois in the mid-1800s as a means of remedying the 'universally unjust' view of American Indians that existed due to 'imperfect knowledge' and 'prejudice.' Morgan aimed 'to encourage a kinder feeling toward' them, emphasizing their 'capacities for future elevation.' From his reformist but ethnocentric and paternalistic perspective, this meant assimilation into the dominant society through schooling and conversion to Christianity. Contemporary critics of development anthropology contend that current efforts constitute little more than a continuation of such ideas. As will be seen, this interpretation is too simplistic. Yet it bears emphasis that both anthropology and development share a common origin in the unequal relations of power among peoples that shaped the modern world.

Colonialism and Its Legacy

As late as 1945, the distinction between 'colonial and non-colonial areas, dependent and independent nations' constituted 'the major and most well-marked division of the lands and peoples of the world' (Kennedy, 1945, p. 306). Indigenous and ethnic groups also held a quasicolonial status within many nation states. Racial and other cultural barriers, along with political and economic inequalities, often set apart the rulers from the ruled. Within this context colonial officials from Britain, Holland, and, to a lesser extent, France, Italy, Belgium, the United States, and other countries called on anthropologists to provide information on local societies, troubleshoot particular problems such as land tenure, and offer training to administrators. Anthropologists were usually supported through institutes or universities, with a few hired directly as members of the colonial administration.

Felix Keesing (1945, p. 392), surveying applied colonial anthropology during the 1940s, identified what has remained as a central tenet of development anthropology: "the existing culture of a people must be made the constant point of reference if administrative and welfare work is to be intelligently planned and effective." He observed that officials overlooked or ignored it because they used their 'own cultural standards, or some distant goal of future improvement, or some overall policy which will apply to every group.' More than six decades later, top–down, universal, and standardized approaches are still the bane of development practice (Banerjee and Duflo, 2011). The widespread, perpetually repeated nature of this 'error' is in itself a testament to the entrenched inequalities and bureaucratic rigidness that typify development situations (Chambers, 1997).

Controversy existed whether anthropologists (who were mainly academically based) should be involved in applied colonial activities. Some saw this as an opportunity to reduce cultural misunderstanding and serve the interests of both local populations and administrators (Gulliver, 1985). Most of the information generated by anthropologists with the assistance of colonial governments was scholastic in nature, lacking direct applicability to official action. Yet, many anthropologists feared that applied work might further imperial exploitation or social engineering. It seemed at odds with the discipline's guiding principles of cultural relativism and scientific objectivity. Some officials also doubted whether 'academic people' had much to offer in terms of practical guidance (Keesing, 1945). Julian Steward (1969) claimed that their skepticism was well founded because most anthropologists of that era were ill-equipped by training and interests to deal with applied issues and cultural change. Even

decades later, anthropologists who took up development work frequently reported feeling poorly prepared by their academic training for it (Green, 1986). As will be discussed below, well into the new millennium some mutual suspicion still exists between anthropologists and other development practitioners, as well as between academic and applied anthropologists (Horowitz, 1999; Lewis and Mosse, 2006).

In assessing colonialism, emphasis in anthropology and development studies has been on its exploitative and hegemonic nature. Because of colonialism's disrepute, other aspects of its complex legacy have tended to be overlooked or dismissed. Jack Goody (1995) has argued, for example, that the relationship between anthropologists and officials was more differentiated and oppositional than typically portrayed in recent studies. Experiences from colonial agricultural, health, and other interventions formed part of local social memories. A collection of studies from East and West Africa, for example, recorded that these projects often mirrored today's decentralized, community-based efforts (Castro, 1998). Relevant lessons from this experience have been missed by planners, either because of its colonial association or due the broader problem of ignoring local knowledge.

Development and Anthropologists: Early Encounters

Post–World War II reconstruction, decolonization (including nationalist struggles), and the onset of the Cold War were the immediate context for the rise of aid programs aimed at promoting development. The Allies produced a new global institutional framework to facilitate problem solving: the United Nations (UN), including its specialized technical assistance agencies such as the World Health Organization (WHO), Food and Agriculture Organization (FAO), and the UN Educational, Scientific and Cultural Organization (UNESCO). Keynesian theories about managed economies shaped the International Monetary Fund (IMF) and World Bank Group to ensure stability and growth. American President Harry Truman's announcement of the 'Point Four Program' in 1949 is often cited as the key moment in launching development as a worldwide enterprise. From its start international aid combined humanitarian motives with political, economic, and other strategic concerns, a situation that has never altered.

Public administrators, engineers, and economists generally guided the new development programs, whose missions were to promote growth and improved living conditions by transferring technology. Anthropologists, when they were involved, usually served as experts on local societies. The new technical assistance agencies such as UNESCO, WHO, and FAO included some anthropologists early on in their activities. Margaret Mead (1953) and others, for example, produced for UNESCO a volume on *Cultural Patterns and Technical Change*. In contrast, international financial institutions took longer to engage them. The World Bank hired its first on-staff 'sociologist' in 1974, and anthropologists did not enter financial institutions in significant numbers until the 1990s (Horowitz, 1999; Marsden, 2010).

Anthropologists entered US aid in 1951, when a small group under George Foster were seconded from a Smithsonian training program in Latin America to evaluate community health care in the region. Their presence was not sustained, as the United States Agency for International Development (USAID) had only one full-time anthropologist on its staff in 1974 (Hoben, 1982). The early anthropologists were often assigned troubleshooter roles, seeking to explain local resistance to projects. Charles Erasmus (1954), one of the Smithsonian anthropologists, soon documented the same problem identified earlier by Keesing: projects often reflected the priorities and assumptions of planners, instead of taking into account local needs, capacities, and preferences. Such findings were not often welcomed, and anthropologists sometimes held the reputation as 'spoilers' or as romantic protectors of local communities. The dwindling of anthropology reflected both a lack of interest on the part of USAID and anthropologists. The latter were drawn away by the boom in academic jobs during the 1950s and 1960s, as well as the controversies of Cold War politics, including the exposing of a few anthropologists who engaged in clandestine research for the US military.

'New Directions' and the Return of Anthropologists

By the early 1970s, disillusionment emerged among the public, politicians, and some development practitioners with the approaches of the previous two decades. These efforts had been characterized by huge projects and centralized planning guided by theories of evolutionary modernization and the 'trickle-down effect.' As Allan Hoben (1982, p. 350) wrote, "the ethnocentric tech-fix orientation of the dominant development paradigm" was challenged. In many countries, indices on the quality of life – infant mortality, life expectancy, per capita income, food production – had failed to improve or had even fallen. The gap between rich and poor, both between and within countries, was widening. In response, the World Bank and the USAID announced in 1973 their intention to direct interventions more specifically at the poor. Under its 'New Direction' guidelines, USAID required all proposed projects to undergo a social soundness analysis, identifying probable impacts on the supposed 'beneficiaries.' In essence, consideration of social variables was brought earlier into the project cycle, influencing project design and even policy. To facilitate these tasks, USAID hired anthropologists, with 50 on staff and at least 100 as consultants by 1980 (Hoben, 1982). Their presence reflected a growing desire by many anthropologists to use their skills and knowledge to address global social issues. A depressed academic job market also fostered a reassessment of desirable employment possibilities.

Anthropologists were pivotal in promoting social- and participatory-oriented approaches to development policy and practice. In doing so, they drew on cutting-edge knowledge, theory, and methods, demonstrating the vital link between academic and applied fields. For example, the World Bank and other development agencies long supported projects such as dams that displaced large populations, yet they lacked guidelines for dealing with resettlement. Drawing on pioneering research by Thayer Scudder, Elizabeth Colson, and others, anthropologists at World Bank led by Michael Cernea (its founding sociologist) spearheaded during the 1980s the formulation of comprehensive policies. Both policy and

practice were also addressed by the Community Forestry Unit (CFU) of FAO's Forestry Department, which was directed by anthropologists Marilyn Hoskins and Katherine Warner from the mid-1980s to 2002. The CFU aimed to strengthen the capacity of the public, resource users, technical personnel, and policymakers to engage in participatory natural resource management by disseminating knowledge of key topics, including gender analysis, indigenous knowledge systems, common property systems, conflict analysis, and livelihoods analysis. It also generated manuals and guides for participatory planning, evaluation, and specialized tasks such as income-generation projects.

Not everyone in development institutions and recipient countries welcomed these innovations. Resistance occurred among those who viewed them as superfluous, wasting time, and increasing costs. Social and participatory approaches also threatened bureaucratic fiefdoms and patronage networks. Evaluative studies by the World Bank and USAID challenged these claims, showing that projects that incorporated social analysis generally proved more effective and attained a higher economic rate of return (Kottak, 1991). Obtaining official compliance with institutional policies and guidelines, as well as with collaborative agreements, still remains a source of contention. The World Bank Group, for example, set up a permanent independent body in 2000 to handle such complaints in a thorough manner.

The Era of Sustainability, Neoliberalism, and Globalization

What constituted development practice shifted yet again during the 1980s. Agencies retained their nominal 'pro-poor' commitment, with emphasis also placed on 'sustainability' in the wake of the 1987 Brundtland Commission report, the 1992 Earth Summit in Rio. New measures, such as the Human Development Index, introduced by the UN Development Programme, highlighted quality of life aspects. Practitioners and activists sought to connect the meaning of development to rights, human capacities, and freedom. The institutional scope of development activities widened, as nongovernmental organizations (NGOs), indigenous peoples, social movements, and other activists increasingly appeared on the scene. Many NGOs followed the funding and pursued donor-driven agendas, but others, both international and local, pressed forward with their own concerns. The rise of Grameen Bank, a grassroots movement for local empowerment, especially focusing on women and families, through microcredit that spread worldwide demonstrated the new creative possibilities of bottom–up development (Yunus, 2007). International donors, for a variety of reasons, endorsed decentralization, creating new political spaces for participation by communities. These trends generally fit well with the campaign by anthropologists and others within and outside international development institutions to 'put people first.' Anthropologists still strove to influence both policy and specific interventions in a wide range of sectors and institutional settings (Grillo and Rew, 1985; Cernea, 1991; Gardner and Lewis, 1996; Nolan, 2002). The Institute for Development Anthropology (IDA), an NGO founded by David Brokensha, Michael Horowitz, and Thayer Scudder in 1976, used its engagement with a large number of multilateral and bilateral aid agencies to promote equity, human rights, and poverty reduction (Brokensha, 2007). IDA operated until 2005.

Yet broad political forces simultaneously asserted another agenda: putting money first, with economic growth as the main and perhaps only goal and measure of development. Neoliberal ideology was in ascendancy in the West, seeking to roll back the Keynesian-managed economy in favor of 'free markets' (which were always selectively defined) and global trade. China's economic reforms and the Soviet Union's collapse heightened the sense of the market's inevitability – some pundits even claimed that the 'end of history' was at hand. While some anthropologists attacked foreign aid as a tool of capitalist domination (Ferguson, 1990; Escobar, 1995), the most significant attacks in terms of policy came from economists who viewed it as supporting bloated, corrupt bureaucracies that choked markets (Moyo, 2009). In general, public support for long-term foreign aid declined, as media coverage of relief and development issues fostered 'compassion fatigue' (Moeller, 1999).

The IMF and World Bank (which retained its guidelines and proponents for socially oriented development) now promoted strict neoliberal agendas in debt-laden countries, forcing them to accept rigid and rapid market liberalization as a condition for aid. The debt crisis surfaced by the late 1970s, the result of mismanagement by both borrowers and lenders, rising energy costs, and falling commodity prices. The 'structural adjustment' program eliminated barriers for trade and investment, reduced state spending on social services, and promoted privatization. Development assistance was increasingly directed away from governments to NGOs (including faith-based enterprises). Donors also favored decentralization, though resources and capacity were often lacking to ensure that it could be done effectively. Economic shocks and declining services often resulted, with devastating impacts, especially on the poor. For example, anthropologists and health professionals documented the declining access of low-income populations to medical care (Kim et al., 2000; Farmer, 2003; Pfeiffer and Chapman, 2010).

An unprecedented expansion in world trade took place after 1980, as multinational corporations outsourced operations to low-wage areas. Some countries, such as South Korea, China, Brazil, and India, managed market integration in a manner that raised incomes for a large number of their citizens. But anthropologists and others documented that neoliberalism and globalization also increased vulnerability worldwide, though in different ways (Comaroff and Comaroff, 2001; Edelman and Haugerud, 2005). Declining social services, removal of food and other important subsidies, privatization of land and other resources, displacement of people due to megaprojects, the spread of the weapons trade, and other trends made life more difficult for people in the world's developing areas. Vulnerability also increased in developed countries due to outsourcing of jobs, the stagnation of working class wages, reduced public services, and other trends. Instability and chaos arising out of neoliberal practices and its politics of inequality, particularly in the 2008 crisis, further extended the sense of insecurity. For anthropologists, these tumultuous changes reduced the

distinction between development and other research contexts. As Chris Hann and Keith Hart (2011, p. 142) observed, "We all seemed to be living in one world unified by capitalism, so anthropologists now study that." Physician and anthropologist Paul Farmer (2003), noted that similar 'pathologies of power' operated across and within societies, generating a kind of structural violence against the poor, who were excluded, and vulnerable.

The New Millennium and Development

In a perceptive article, Curt Grimm (1998) observed USAID's declining interest in, and capacity for, socially oriented development. USAID had not rejected the lessons of its 'New Directions' agenda but reframed it into an emphasis on market-oriented 'customer service.' A contrast can be made with British foreign aid, the Department for International Development (DfID), which had build up its social development capacity, while promoting holistic concepts such as 'sustainable livelihoods analysis' in their planning. By the new millennium, DfID had assumed a leadership role in international development once held by their American counterparts. Even as World Bank had promoted severe structural adjustment programs, its anthropologists and others had continued to press its leadership to acknowledge equity issues, including promoting local empowerment, respecting indigenous rights, and so on (Davis, 1998). Their efforts demonstrated that an institution such as World Bank was not a monolith, but composed of competing interests. In fact, anthropologists widened their scope of study to probe the agencies, examining them ethnographically as sites of contestation rather than as 'totalizing' entities of capitalism (Lewis and Mosse, 2006; Mosse, 2011).

National leaders meeting at the UN in 2000 adopted the Millennium Declaration, which committed them to pursuing eight development goals through 2015. The Millennium Development Goals (MDGs) offered a reaffirmation of quality of life issues, focusing on poverty/hunger, education, gender equity, child mortality, maternal health, disease, environmental stability, and 'partnership' issues. Ironically, given the latter goal, the MDGs were mainly shaped by members of the Organization for Economic Co-operation and Development, a group of 30 countries, most of them among the most prosperous in the world. Critics, including anthropologists, expressed skepticism, often portraying it as yet another example of a donor-driven process imposed on developing countries (Black and White, 2004). With their emphasis on target delivery, the MDGs appeared to some anthropologists as a return to social engineering. There also seemed to be a disconnect from the broader context of neoliberalism, with its destabilizing inequalities, ongoing financial chaos, development-related environmental change (including climate change, deforestation, and biodiversity loss), and other issues.

The Global War on Terror in the wake of 11 September 2001 added to the confusion. Policymakers increasingly sought to link development activities to counterinsurgency 'hearts and minds' campaigns, a practice dating back to anticolonial struggles. The military were asked to fulfill 'humanitarian interventions,' a practice long regarded as controversial. The open recruitment of anthropologists and other social scientists into the Human Terrain Project and related 'security' endeavors sparked heated debate on political and ethical grounds within the discipline (Price, 2011). The 'War' also helped draw attention to another manifestation of globalization: the presence of sizable transnational immigrant communities in developed countries who kept up financial and political, as well as social, links to their home areas. Remittances by international migrants now represented a substantial economic force, totaling more than $125 billion in 2005, exceeding the contributions of donor countries to international development (Cohen, 2011).

In a provocative analysis, Scudder (2010), drawing on his five decades of experience as an applied anthropologist, explored the possibility that current crises foreshadow a coming era of declining global living standards. To cope, 'transformational changes' must occur in terms of values, political economy, and social relations. Some anthropologists and activists already portrayed 'postdevelopment' communities and social movements, where people possess values opposed to the hegemonic discourse of development and consumerism (Escobar, 1995). Others assert that most people worldwide still seek to be a part of the global consumer society, thus adhering to, as well as pushing forward, the 'old premise of development' (Hann and Hart, 2011, p. 120). Goody (2010) and others suggest that the economic rise of East Asia and India also offer a significant challenge to the view of development as synonymous with Westernization.

The Anthropology of Development

No singular subdiscipline of development anthropology has ever emerged in the sense of 'a coherent or distinctive body of theory, concepts, and methods' (Hoben, 1982, p. 349). What constitutes an 'anthropology of development' is simply the sum total of the diverse perspectives and experiences of those who engage in, write about, or teach on policies, practices, and discourse dealing with development and topics such as globalization. In this regard, anthropological approaches and activities related to development, as well as colonialism and globalization, closely reflect what is happening in the wider discipline as a whole. At the same time, anthropological engagement with development has shaped to some extent thinking and practice within the discipline. It also influenced, both for better and worse, how other fields understood development and globalization.

As mentioned earlier, applied anthropologists were often initially assigned the task of explaining local resistance to development projects. Given the discipline's predominant ideas in the 1950s and 1960s, they often did so by emphasizing local values and cultural patterns. Academic studies by Clifford Geertz, Oscar Lewis (who devised the concept of the 'culture of poverty'), and others dealing with 'modernization' and development themes covered similar ground. However, unintentionally, these analyses reinforced prevailing ethnocentric ideas about the people and processes involved in development. Anthropologists eventually moved on (see later text), but

specialists in other fields clung to the idea of culture as the primary barrier to the development. Lawrence Harrison and Samuel Huntington (2000) heralded these views in an influential collection, with Daniel Etounga-Manguelle (2000), for example, arguing that Africa needed a kind of 'cultural structural adjustment program' to mend its feckless ways. Ironically, the World Bank (purveyor of structural adjustment programs), issued a volume featuring anthropologists such as Mary Douglas and Lourdes Arizpe, as well as others, refuting such arguments (Rao and Walton, 2004). The debate about culture's role in development still continues.

Anthropological concerns about development have shifted in the past three-plus decades as the field itself has undergone substantial alteration. Diverse theoretical currents have flown through it, including variants of Marxism, feminism, post-modernism, and practice theory, inspiring innovative forms of analyses, including actor-oriented approaches and discourse analysis. Anthropologists have put together these concepts and tools for very different ends. Arturo Escobar (1995) used discourse analysis to expose development as a discourse and institutional practices that perpetuate domination of the Third World. He argued that anthropologists should not be involved with development agencies. In contrast, Katy Gardner and David Lewis (1996) agreed with many of the criticisms of the development industry, but reached a different conclusion: contending that the insights of discourse analysis, combined with ethnographic research, offered new possibilities for supporting effective participatory efforts. Gardner and Lewis felt that the involvement of anthropologists from the global 'South' especially offered innovative avenues for change. In some countries, such as Mexico, anthropology has a long, if contentious, involvement with development issues (Nahmad Sittón, 2011). Other countries are at a relatively early stage of building their capacity in anthropology, though applied issues still often loom large (Hill and Baba, 2006).

Overall, the rise of neoliberalism and globalization has narrowed the gap between development and other domains within the discipline, as convincingly displayed in Marc Edelman and Angelique Haugerud's (2005) edited volume. In addition, anthropologists are increasingly seeking to make their work 'relevant' to a wider public, including the populations that they are studying (Low and Merry, 2010). The discipline's strength has always been in the ability of analysts to illuminate site-specific conditions through ethnographic research. The shrinking difference between academic and applied studies is especially evident in studies dealing with fields and topics such health, AIDS, migration, postsocialist transitions, social movements, conflict, livelihoods, and pastoralism.

Conclusion

The appointment of anthropologist and physician Jim Yong Kim as president of the World Bank in July 2012 may signal a significant shift in the practice of international development. Taking on a position always held by economists, Kim has been a critic of policies that promoted growth yet undermined the health status of the poor. In many ways, his new role reflects the outcome of a long, contentious history of anthropological involvement with development issues. Dating back to Morgan's Iroquois study and no doubt beyond, anthropologists have sought to use their skills and knowledge to assist societies marginalized by market and state expansion. Those interested in applied anthropology have not only faced skepticism and skepticism from colonial and development officials, but also from their own academically based colleagues. The experience of anthropologists in development, especially in the era of neoliberalism and globalization, has narrowed, though not eliminated, such tensions. As anthropology faces growing uncertainty in terms of future academic job growth, greater attention will have to be given to prepare students who may seek positions in the wide range of organizations and groups now involved in development-related activities.

Abstract

This contribution identifies development as an *emergent* and *contested* key concept in the social and environmental sciences. 'Development studies' describes a field that includes multi-, inter-, and transdisciplinary approaches to economic growth, basic needs, inequality, human development, rights, resources, livelihoods, and sustainability, focusing mainly, but not exclusively, on 'developing' countries. The scope and content of development studies is described and the main schools of thought, theoretical debates, concepts, and indicators are discussed in historical context, ranging from the colonial appropriation of natural resources to modernization and its critiques, to current agendas for sustainable and rights-based human development.

Introduction

'Development' has been a core concept for the social sciences since the Enlightenment and has been named as 'the central organizing concept of our time' (Cowen and Shenton, 1995: p. 27). Development can be understood as an *emergent* and *contested* concept – different meanings have emerged through continuing critical debates. In mid-eighteenth-century European thought, 'development' signified a general process of unfolding or becoming. It acquired evolutionary and biological meanings as these ideas took shape in the later eighteenth and nineteenth centuries. Ideas of progressive development became highly controversial as evolutionary theory turned into a major battleground for the contending forces of science and religion. The twentieth-century politics of decolonization brought further contention as neoimperial and national interests competed to claim the project of 'development.'

'Development studies' constitutes a relatively young field (Haddad et al., 2011). The term has been used, since the late 1940s, to describe a multidisciplinary field within the social sciences, addressing the economic, social, and political concerns of the 'developing' countries. A looser practical definition of development studies describes it as "all forms of writing and talking about development, as well as forms of action (such as training and even project work) which grow out of these processes" (Edwards, 1989: p. 117). 'Development studies' covers a spectrum of academic and nonacademic theory, policy, and practice. It is cross-disciplinary, involving a spectrum of multidisciplinarity, interdisciplinarity, and transdisciplinarity (Sumner and Tribe, 2008: pp. 35–37) across subject areas including (but not limited to) economics, politics, sociology, anthropology, agriculture, health, education, law, geography, and area studies. Hettne defines development studies as "…a problem-oriented, applied and interdisciplinary field, analyzing social change in a world context, but with due consideration to the specificity of different societies in terms of history, ecology, culture, etc." (1995: p. 4). This definition encapsulates three paradoxes: the field of development studies is cross-disciplinary, yet rooted in disciplinary knowledge; global in scope, yet embedded in local contexts; generalizing and theoretical, yet practical and problem oriented.

Development studies' emergence in the 1940s was influenced by changing colonial policy, and also by a move toward social democracy and welfare states within the imperial core which became defining characteristics of 'developed' countries. Dominant theories about development appear to follow a cyclical pattern, alternating between *laissez-faire*, growth-oriented approaches and more interventionist, redistributionist, and equity-oriented ones (Cooper and Packard, 1997: pp. 29, 30).

The ideas and institutions of development studies were strongly influenced by the Cold War between the 1940s and the end of the 1980s, and from then on by globalization, neoliberalism, the rise of new, nongovernmental development actors in the 1990s, and recent social market and social entrepreneurial approaches. Current debates in development studies also highlight the role of faith (Tadros, 2011), philanthropy (Edwards, 2011), and the influence of economically powerful, large Southern states such as Brazil, India, and China on development (UNDP, 2013). Conventionally, development studies has been more concerned with the 'Third World,' 'Global South,' or 'developing countries' of Africa, Asia, and Latin America and less concerned with the problems of the 'Global North' – the European, North American, and Antipodean 'developed countries.' The term 'Third World' derives from the French demographer Alfred Sauvy's expression '*Tiers Monde*.' Sauvy likened the masses or 'Third Estate' of the 1789 French Revolution to the countries that had assembled in Bandung in 1955 to declare their 'nonalignment' with the non-Communist 'First World' or the Communist 'Second World' (Sauvy, 1952; see also Hettne, 1995). These distinctions between the 'developed' or richer and 'underdeveloped' or poorer countries of the world, and between the three 'worlds' of development became problematic with the end of the Cold War, the disappearance of the 'Second World,' the spread of globalization, and the rise of middle-income countries by the end of the 1980s.

Globalization has surfaced shared crises and challenges such as climate change, financial instability, resource depletion, and food crises, and made the need for coordinated responses and alternative approaches more salient. The global economic turmoil of 2008 stimulated a degree of critical self-reflection in the North and swung debates back to the questions that

emerged following earlier historical crises. Current critiques of growth (e.g., Jackson, 2011) revive earlier debates on the 'affluent society' and the downsides of economic growth (Galbraith, 1958; Mishan, 1967). Environmental concerns that emerged in the 1960s (Carson, 1962/2000) have become accepted by the mainstream (e.g., Collier, 2011). The questions leveled by nonorthodox development economists at their own discipline about inequality and unemployment (e.g., Seers, 1963, 1969) have been revisited by critical commentators on globalization and inequality (Kaplinsky, 2005), while the fundamental assumptions and disciplinary primacy of economics, the dominant discipline in development studies since the 1950s, have been similarly questioned (Krugman, 2009).

The questions of economic, social, and political progress addressed by development studies have been, from the outset, accompanied, heightened, and complicated by political processes of decolonization and the interplay between national self-determination, human rights, democratization, and citizen politics. Since 2000, development studies has taken a more technical and less political track, focusing on the Millennium Development Goals (MDGs, 2000–15), and questions of 'effectiveness,' financing, and 'good governance.' However, questions about ecological damage, depletion of natural resources, and the fundamental role of the natural environment in sustaining human life, health, and livelihoods have not, so far, been fully addressed. The integration of environmental and natural resource dimensions, and their connection to problems of inequality, continue to pose a central challenge to development studies in the twenty-first century.

Historical Origins of Development Studies

Current patterns of global development have been profoundly shaped by the history of capitalist and colonial power relations. 'Development' is conventionally understood as a post-Second World War artifact, oriented toward national states' pragmatic concerns with planned economic growth and international cooperation. However, this postwar agenda was not completely new, but built upon historical patterns of colonial and imperial rule which fundamentally structured global and local economies, societies, and cultures over several centuries. Imperialism and colonialism profoundly reshaped the relationships between people, nature, and natural resources (Woodhouse and Chimhowu, 2005: p. 180). The colonial concept of development referred to the *development of economic resources*. 'Developing' a territory or region meant 'opening up' natural resources for the colonial economy, mobilizing labor, possibly by promoting large-scale labor migration, and building infrastructure such as railways, ports, and roads to facilitate resource exploitation (Arndt, 1981: p. 462). Colonial regimes secured their access to resources such as land, forests, water, and minerals by codifying laws, procedures, and institutions of colonial administration, displacing the traditions and norms that underpinned social relations and people's access to livelihood resources (Randeria, 2003: pp. 40–43). Imperialists generally viewed their 'development' activities to be humanitarian and benevolent, a view supported by the expansion of both missionary activity and social science in the late nineteenth and early twentieth centuries.

Social welfare became an explicit consideration with the advent of a new mode of colonialism, the '*dual mandate*,' which cast the colonizers in a tutelary, protective role, even as they sought out resources and profits from their colonies (Arndt, 1981: p. 463). This ambiguous rationale continued into the era of decolonization under the provisions of 'trusteeship.' The British Colonial Development and Welfare Act of 1939 defined trusteeship in terms of a colonial responsibility for 'minimum standards of nutrition, health and education' (Hancock, 1942 cited in Arndt, 1981: p. 463). After the Second World War, 'development' was presented as the solution to a global problem of 'underdevelopment' in a new era of decolonization and international cooperation. An international 'New Deal' was promised by the new global power, the United States. At his 1949 inaugural address, President Truman declared that "[t]he old imperialism – exploitation for foreign profit – has no place in our plans. What we envisage is a program of development based on the concepts of democratic fair-dealing" (cited in Rist, 1997: p. 71). Nevertheless, the political and economic self-interest of leading powers remained important drivers of development in the former colonies, and geopolitical competition influenced the establishment and emergence of development studies programs (Cooper and Packard, 1997; Gilman, 2007). While many consider development studies to be largely an 'asymmetric business' involving Northern social scientists studying Southern countries' development problems (Forster, 1997), important exceptions include the Latin American 'dependency school' and Islamic critiques of western modernity (Connell, 2007). Dependency theorists emphasized the systemic links between colonial resource appropriation, unequal exchange, and global inequality, while Islamic critics highlighted the undesirability of western materialism and consumerism, while emphasizing responsibility and stewardship as spiritual values. The current combination of economic and social crisis in the North and the 'rise of the South' (UNDP, 2013) have deepened skepticism about the 'Eurocentric' model based on 'transferring' knowledge from the 'North' to the 'South,' favoring a more equitably global, interdependent, and partnership-based approach to development as a shared concern of all countries – rich, poor, or 'transitional.'

Major Theoretical Approaches and Debates: From Modernization to Dependency Critiques to Human Development

Development studies' formative period – from the late 1940s to the early 1970s – could be described as the 'golden age' of welfare capitalism (Marglin and Schor, 1990) characterized by coordinated state action for national development. National accounting was established as the basis for planned national development. Advances in 'modernization' and industrialization could be measured in terms of aggregate formal economic production, gross domestic product (GDP) and retained national income, and gross national product (GNP, also termed gross national income). National

accounting techniques developed in the USA and Europe in the 1930s and 1940s in response to the Great Depression, the rise of Keynesian macroeconomics, and demands for resources for major war efforts. However, despite the increasing sophistication of national economic accounting techniques, they also presented certain limitations. Critiques emerged as the tensions between differing social concerns, theoretical issues, and data constraints became increasingly evident (Vanoli, 2008).

Modernization theory, originating in the 'modernization school' of the 1950s and 1960s, predominated in development studies up to the 1990s, with one notable modification – the neoliberal turn against state developmentalism and toward free-markets at the end of the 1970s. Modernization theorists had incorporated the basic assumptions of nineteenth-century evolutionary and imperial social science, but shaped them according to the emerging geopolitics of the Cold War (Gilman, 2007). An example is Walt Rostow's *Five Stages of Economic Growth* which bore the subtitle 'A Non-Communist Manifesto' (Rostow, 1960). Like their nineteenth-century intellectual forebears, modernization theorists assumed that all societies began as 'primitive societies' that would gradually make the transition to cultural modernity and 'advanced' economic status, defined as high and growing national income, maximizing the commodification and exploitation of natural resources, industrial production, and the transition to a consumer society. The need to assist the economic growth process came from the perceived threat of Communist revolution; hence Cold War superpower rivalry drove programs of international assistance for 'development' in the Third World. More concerned with political stability than social justice, modernization theorists assumed that the benefits of economic growth would trickle down to reach the poor. However, statistics that were now being systematically collected showed that poverty, inequality, and deprivation had not diminished, but persisted and even increased in many countries.

The postwar international development regime's claim to fair-dealing under the *Pax Americana* was tested by Structuralists who noted the problem of asymmetry in the global economy. In 1950, Hans Singer and Raul Prebisch came up with the 'Singer–Prebisch thesis' which postulated that the primary product exporting 'developing' economies experienced declining terms of trade vis-à-vis advanced economies exporting manufactured goods. The Structuralist findings led neo-Marxist dependency theorists like Paul Baran and Andre Gunder Frank to argue that the structure of the global economy was essentially neocolonial, presenting intrinsic difficulties for developing countries (e.g., Frank, 1966). National economies were therefore advised to 'delink' their economies and shift their economic base away from primary commodity exporting and toward industrial production with national tariff protection. The 'import substitution industrialization' (ISI) strategy gained political support in the 1950s and 1960s, but declined in favor, partly due to a lack of success of ISI policies, but also because transnational corporations countered developing country protectionism with the new strategy of 'foreign direct investment' – this became the predominant approach by the later 1970s.

The new discursive forums convened under the auspices of the United Nations, such as the UN Economic Commission for Latin America (ECLA or, in Spanish, *CEPAL*) and the UN Conference on Trade and Development, enabled a developing awareness and solidarity among developing countries, based on shared critical analyses of unjust structural tendencies and aggregating developing country demands for global reforms.

In 1966, Andre Gunder Frank popularized the perspective of the Latin American 'dependency theorists' with his essay on '*the development of underdevelopment*,' which highlighted the unequal, neocolonial nature of global development (Frank, 1966). Hettne (1995) characterizes dependency theory as principally a Latin American contribution – 'the voice of the other' (see also Connell, 2007).

In 1972, the Senegalese judge Keba M'Baye connected development with the emerging human rights agenda of the United Nations, through the idea of a Right to Development (Barsh, 1991). Developing countries articulated a collective demand for a New International Economic Order (NIEO) at the UN General Assembly in 1974 (United Nations, 1974). The demands included fairer financing and terms of trade; more controls over multinational corporations; and greater equality and influence for developing countries within the United Nations. The UN Human Rights Commission began to examine development from a human rights perspective in 1977, resulting in the 1986 UN Declaration on the Right to Development (United Nations, 1986). However, like the NIEO, the Right to Development came to be seen as little more than 'an expression of South frustration in the face of intransigent North power' (Barsh, 1991: p. 322). The Right to Development was viewed with suspicion by orthodox (and predominantly Northern) human rights advocates, who believed that the 'first-generation' individual civil and political rights (which were supported by the capitalist 'First World' powers) were more workable and 'justiciable' than 'second-generation' economic, social cultural rights (which were attributed to the socialist 'Second World'). Third-generation 'solidarity rights,' which were identified with the Third World nations, were thought to be even less likely to achieve justiciability. Nevertheless, theoretical bridges between human rights and development continued to strengthen, particularly through human development and capability approaches. The human development approach was adopted by the United Nations Development Programme (UNDP), which published the annual Human Development Index and Human Development Reports from 1990 onwards (see http://hdr.undp.org/en/). Amartya Sen's idea of 'development as freedom' (1999) set out an ethically grounded, philosophically liberal, and individualist approach to human development.

The British development economist and founder of the UK Institute of Development Studies, Dudley Seers, directly challenged mainstream development theory, which was dominated by the concern for national economic growth:

> Economic growth will not merely fail to solve social and political difficulties; certain types of growth can actually cause them. Now that the complexity of development problems is becoming increasingly obvious, the continued addiction to the use of a single aggregative indicator [economic growth] … begins to look like a preference for avoiding the real problems.
>
> Seers, 1963: p. 77

The later 1960s saw the development of significant innovations in conceptualizing and measuring development. Seers (1969: pp. 3, 4) argued that the three major problems of development were poverty, unemployment, and inequality: "if one or two of these central problems have been growing worse, especially if all three have, it would be strange to call the result 'development,' even if per capita income soared." Morris's 'Physical Quality of Life Index' (PQLI) offered another alternative approach, evaluating development on three dimensions: infant mortality rates, life expectancy at age one, and literacy (Estes, 2003). Morris devised the PQLI to reflect the results of development efforts, instead of relying on notionally available economic resources that might not be mobilized for desirable human outcomes. Comparisons of PQLI data across countries showed that there was no obvious correlation between increasing aggregate income and welfare outcomes. This suggested that quality of life was only indirectly determined by high economic growth, and that wise government policies and spending priorities were probably more important factors. Morris was aware of the need to avoid ethnocentric assumptions, since not all countries might wish to develop in the same way. However, he insisted that the measure should be internationally comparable, settling on indicators of human survival and functioning to reflect basic conditions "from which further forms of social satisfaction could be determined" (Morris, 1978: pp. 225, 230–231).

In practical terms, the 1974 NIEO demands for global economic restructuring saw expanding developing country expectations at a time when developed country support was shrinking. In 1976, the International Labour Organization (ILO) pushed forward the concept of 'basic needs,' arguing that "it is no longer acceptable in human terms or responsible in political terms to wait several generations for the benefits of development to trickle down until they reach the poorest groups." Basic needs were defined as "minimum food, shelter, clothing, access to essential services such as transport, education, sanitation, health care, an adequately paid job, healthy environment and popular participation in decision making" (ILO, 1976). The expansive definition of 'basic' needs reflected the content of the two major global human rights treaties agreed in 1966, after almost two decades of contention – the International Convention on Civil and Political Rights and the International Convention on Economic, Social and Cultural Rights.

Despite the fractiousness that had characterized North–South relations in the decolonizing period from 1945 to 1973, these decades delivered sustained economic progress with improving welfare for large parts of the world. However, the end of the 1970s saw the introduction of neoliberalism, fiscal austerity, welfare cutbacks, and intensified militarization, all contributing toward a darker and more pessimistic context of 'de-development.' Global recession, debt crisis, and neoliberal structural adjustment policies caused the 1980s to become known as the 'impasse' or 'lost decade' of development (Schuurman, 1993).

The 1990s saw many critical development theorists taking a 'postdevelopment' turn, declaring 'development' to be 'a ruin in the intellectual landscape' (Sachs, 1999). Development theory incorporated postcolonial critiques of Eurocentrism, taking a 'cultural turn' toward nativist and populist conceptions of community and grassroots empowerment. Some political economy, class-based, and feminist theorists remained skeptical of postdevelopment's reactionary, conservative, and identitarian aspects (Brass, 2007). Development reformists, on the other hand, stuck to critically examining the dilemmas of doing development and continuing to strive for progress in difficult circumstances. Reformists continued to seek improvements in international cooperation, to alleviate suffering, and protect the basic needs of the most vulnerable, within the context of constrained development (Cornia et al., 1987). The basic needs agenda was also expressed through rights-based approaches as some attempted to define a 'minimum core' of socioeconomic rights (Young, 2008). Official development assistance declined after 1989, as Cold War geopolitical motives for assistance waned. This led to the creation of the Millennium Development Goals (MDGs) to revitalize commitments to development and focus international action on poverty alleviation. Since their introduction in 2001, the MDGs have become an accepted framework for international development as even those who initially hesitated or opposed the MDGs ended up using them (Fukuda-Parr, 2012).

Amartya Sen, Mahbub ul-Haq, and Martha Nussbaum are the best-known exponents of the 'human development paradigm.' The human development approach, launched in 1990 under the auspices of the UNDP, incorporated aspects of the PQLI and responded to the question about how economic growth related to other human needs or goals. Economic growth and income are seen as instrumental means to achieve development, but not its ultimate goal. Sen's 'capabilities approach' informed the design of the Human Development Index (HDI), a composite measure of welfare and income integrating social and economic dimensions of well-being. The HDI components are health, indicated by infant mortality and life expectancy; knowledge, indicated by school enrollment and adult literacy; and income, indicated by GNP. The HDI reunited welfare components with income measures, because the PQLI on its own "misses the synergy between social and economic progress" (Ul-Haq, 1995: p. 128). Like the PQLI, the HDI was intended to widen the scope beyond GDP/GNP as the focus of development, and support investments in health and education, without rejecting economic growth. The human development approach aspired to be "the most holistic model that exists today … a practical reflection of life itself" (Ul-Haq, 1995: p. 21). Since 1990, new dimensions have been added, incorporating expanding understandings of poverty, gender, and inequality. Capability theory has expanded into a large body of work on concept, measurement, theory, and policy, focused on particular areas such as health, hunger, gender equality, and education.

Further Directions: Sustainable Human Development and Rights-Based Approaches

The concept of 'sustainable development' entered into the development mainstream with the publication of the Brundtland Commission's report in 1987 (WCED, 1987). This concept brought the 'Southern' critique of unequal, neocolonial, and 'dependent' development together with other systemic

concerns about population growth, pollution, and ecological limits to growth, concerns that were global in scope, but largely Northern in their origin. The debate was influenced by the publication of *The Population Bomb* (Ehrlich, 1968) which revisited Malthus's controversial 1798 *Essay on the Principle of Population*:

> …that it can be a very bad thing to have more than a certain number of people alive at the same time, that Earth has a finite carrying capacity, and that the future of civilization was in grave doubt.
> Ehrlich and Ehrlich, 2009: p. 63

Malthus had opposed the provision of famine relief in the nineteenth century because he regarded famine, war, and disease as functional 'natural checks' on population. Almost two centuries later, Ehrlich suggested that the only measures that could prevent civilizational collapse were either mass birth control ('the birth rate solution') or allowing the poor to die ('the death rate solution') (Ehrlich and Ehrlich, 2009). The burden was heaviest for the poorer countries, which had not yet undergone the demographic transition (Dyson, 2010). At its extremes, Malthusianism coincided with eugenicist views that the 'least-fit' individuals must perish in order that the 'fitter' survive (Desrochers and Hoffbauer, 2009: p. 39). Malthusian pessimism was countered by 'cornucopians' who viewed population growth optimistically, as providing labor and 'talent' for development, more than compensating for the burden they represented in terms of food consumption (Dyson, 2010). Cornucopian thinking has continued to develop in the form of 'ecological modernization' and 'weak sustainability' theory, which suggests that increased consumption burdens will be compensated ('substituted') by increased knowledge and improved technology (Neumayer, 2003).

Human rights and development connected in the 1972 'Right to Development' proposal to the United Nations, articulating the human right to "a particular process of development, in which all human rights and fundamental freedoms can be fully realized." The 1986 Declaration on the Right to Development announced a humanist revolution in the meaning and purpose of development, in stating that "the human person is the central subject of development and should be the active participant and beneficiary of the right to development" (United Nations, 1986). Governments were tasked to empower citizens and guarantee them equal benefits from development as rights. In the 1970s and 1980s, the right to development tended to be claimed by developing country governments, not individual citizens, as a way to assert the 'developing country position' in international negotiations, especially after the NIEO reforms proposed in 1974 failed to materialize. However, by the 1990s more attention began to be paid to participation and benefits in more specific contexts, especially in the three 'immediate action areas' of hunger and food, health, and education (CDHR, 2004).

A recurrent theme throughout the theoretical debates in development studies has been the insufficiency of income measures and the turn to alternatives. *Sustainable human development* has been proposed as the ultimate goal; however, human development and capability theory's expansive and freedom-based conceptions of human progress may come up against environmental limits (Neumayer, 2010). Some theorists have returned to the basic needs concept, and attempted to define a 'minimum core' of human needs or values, that can be used as the basis of substantive, justiciable rights claims, defining national and international responsibilities (Young, 2008).

Advocates of sustainable human development hope that the divergence between economic and human development can be resolved by putting economic development 'back in its place' as a means of human development. However, economic growth remains a fundamental component of human development that may be impossible to sustain. From an ecological perspective, recognition for absolute planetary carrying capacity is essential. For development studies to deal with these limits, it must find new ways to integrate ethics, economics, and politics, recognizing that development problems cannot be solved by the application of scientific or technical solutions on their own. Concepts of 'environmental space' and 'new economics' try to bring together these concerns to inform and achieve equitable and sustainable development (Khoo, 2013).

Conclusion: Development Studies, Complexity, and Uncertain Futures

The critical debates in development studies have consistently questioned the meaning, relevance, and legitimacy of 'development' and asked whether development studies is asking the right questions about the right problems, whether it is justifiable as an interdisciplinary subject for study, research, and practice, and whether such a subject deserves support. Such questions are unsurprising, given the starting point for this entry is that 'development' is an emergent and contested concept. We should expect the legitimacy and relevance of 'development studies' to be contested, given the power, ideology, and resources that are at stake. Complexity and uncertainty are intrinsic to the development effort, and development studies, as a field, has been paradoxically constituted by both fierce disagreement and pragmatic consensus. Development studies' cross-disciplinary character is vindicated by the complex and multifaceted character of pressing global challenges and problems. The durable big topics and concerns include poverty, inequality, demographics, ecology and sustainability, democratization, gender equity, globalization, and rights. A rights-based approach suggests a substantive focus on the three 'immediate action areas' of the 1986 Right to Development (CDHR, 2004): food (including hunger and agriculture), health, and education – all are ultimately bound by considerations of 'environmental space,' social justice, and basic needs.

Current debates within development studies have focused on a need to 'rethink' and reimagine development studies (Haddad et al., 2011) in a world of growing complexity, increasing population, and limited resources. Although much criticized, the MDGs offered an achievable approach for development studies (Fukuda Parr, 2012) because they reduced the complexity of development challenges down to eight goals with concrete global targets, to be achieved between 2000 and 2015. The MDGs prioritized poverty, some communicable diseases, and gender equity and improved coordinated action, but their narrow emphasis detracted from other important concerns such

as inequality, or broader conceptions of health or ecology, and they oversimplified the policy debates. Haddad et al. (2011) indicate that development studies has to move away from the historical distinction between 'developed' and 'developing' countries and beyond the limited policy mindset of official development assistance to a broader global vision. The academic field of development studies has been challenged by the policy and practice community to become less 'problem focused' and more 'solution oriented' and provide answers. The theory-applied practice tension has also pushed development studies to embrace a new organizational approach that moves away from the North-dominated, 'expat-expert' driven and top-down approaches that have predominated since the 1940s and 1950s. Development studies has moved slowly toward a 'co-constructive' approach that recognizes and involves different actors on a more truly global and equal basis, through methods of research and decision-making that link bottom-up grassroots and top-down policy processes (see Haddad et al., 2011; UNDP, 2013). The UNDP (2013) suggests that development studies must learn more from the 'rise of the South,' identifying four important areas for future development studies to concentrate on – enhancing equity, enabling voice and participation, confronting environmental pressures, and managing demographic change. The UNDP suggests that future development studies could focus on issues surrounding the provision of global public goods and concentrate on finding ways to unlock stalemated global issues (UNDP, 2013: p. 20).

However, Severino and Ray (2009) argue that greatly increased funding for 'international public policies' has coincided with a lack of clarity and unity of purpose, due to the 'triple revolution' which has multiplied development objectives, players, and instruments in recent times. Another important question for development studies is how 'development' interacts with humanitarian theory, policy, and practice. Humanitarianism and development have tended to occupy separate and parallel worlds; however, current trends have seen a swing toward the integration of humanitarianism and development, with a practical focus on conflict reduction, postconflict reconstruction, social protection, and 'governance' issues (Barnett, 2013).

'Development' denotes a collective striving, a concern to envision, and programmatically pursue, societal progress. Yet 'progress' is difficult to define, and its meaning is shaped by both long-term trends and short-term crises and fads (Eade and Cornwall, 2010) and by significant contests over power, ideology, and resources. As a cross-disciplinary, contextually grounded but global field, development studies continues to be a lively, contentious, and open field, addressing necessary and relevant dilemmas of economy, society, politics, and environment, while facing fundamental questions about humanity, justice, and the responsibility for collective action.

Development Theory in Geography

Abstract

Development geography since the end of World War II has been transformed from a subdiscipline that largely borrowed from major themes in development theory to one that helps develop major themes, this change reflecting the increasing salience of sociospatial issues in an era of globalization.

Introduction

The issues which geographers have placed on the agenda of development theory in the post-World War II period fall broadly under the heading of what can be called the 'spatial problematic.' This problematic includes issues such as reasons for developmental patterns of diffusion and/or geographic difference, as well as the relationships between development processes in different locations. The spatial problematic can also be taken to embrace issues of human–environment interaction in the development process, including patterns of resource use, food production and consumption, and generation of environmental hazards. By the end of the Cold War 'development decades' (Sheppard et al., 2009), in the 1980s and early 1990s, neoliberal globalization generated a context in which geography as a field, and as an aspect of social reality, had become central to the formulation of theoretical positions surrounding development issues, a position of theoretical centrality that geography has maintained into the twenty-first century.

The Development of Post-World War II Development Geography

Given the obvious significance of topics falling within the spatial problematic, it is surprising that until the last two decades of the twentieth century the contributions of geographers to development theory in the English-speaking world were comparatively limited. A 1960 report by leaders in the field estimated that only two dozen studies had been published on the issue of economic development between 1949 and 1959, and only half of these were on development in 'underdeveloped areas' (Ginsburg, 1960, p. ix). Similarly, a 1967 article by D.E. Keeble showed that between 1955 and 1964, the journal *Economic Geography* published 251 major articles, only 10 of which (under 4%) were concerned in whole or in part with issues of economic development, while the topic was addressed in only 6 out of 242 articles (2.5%) in the *Annals of the Association of American Geographers* (Keeble, 1967, p. 243). A review of research published in *The New Zealand Geographer* cited a similar neglect of development theory (Chapman, 1969).

The theories of development employed in this early postwar literature were fundamentally those that had been developed in disciplines such as economics, political science, and sociology. In particular, most work by geographers in the 1960s fell more or less explicitly into the category of 'modernization' studies, adopting the view that all countries could and should follow more or less the same course of development as the advanced industrialized capitalist countries, passing through 'stages of growth' which lead from premodern, preindustrial, and relatively stagnant to industrial, modern, and dynamic. Geographers gave modernization approaches a spatial bearing through examination of issues such as urbanization patterns (Berry, 1961), regional development (Friedmann, 1966), and the development of transportation systems (Gould, 1960; Taafe et al., 1963), as well as through statistical analyses of the diffusion of modernization (Gould, 1964).

By the time development geographers had embraced modernization approaches, however, modernization theories had already been under serious attack for a decade or more by various 'core–periphery theorists' – including structuralist and dependency authors – who placed the claims of modernization theory up against the realities of development in peripheral regions of the global economy such as Latin America, and found the theory wanting. Structuralists argued that the historical legacies of colonialism and imperialism – such as technological backwardness, maldistribution of wealth and income, and a large, underemployed rural labor force – made the development of modern industry in the periphery a much more problematic process than modernization theorists had suggested (Sheppard et al., 2009, pp. 84–86). Dependency authors more explicitly identified the process of development in core industrialized capitalist countries as an obstacle to development in countries of the global periphery, and more radical dependency and underdevelopment perspectives which became popular by the late 1960s went so far as to suggest the impossibility or unlikelihood of capitalist development in the global periphery, precisely because of its relations with the global core (Sheppard et al., 2009, pp. 86–89).

These structuralist and dependency perspectives, even though not originally articulated by geographers, helped bring greater attention to geographic differences in patterns of development and to relationships between development processes in different places. This spatial dimension was naturally attractive to many geographers and spurred a significant amount of core–periphery analysis, including theories regarding revolutionary change in Third World urban centers (Armstrong and McGee, 1968), general theories of imperialism (Blaut, 1970), and critiques of Eurocentrism in geographical research (Connell, 1971). By the middle of the 1970s there were a large number of works adopting either

structuralist (e.g., Brookfield, 1975) or dependency approaches (e.g., Santos, 1974). This burst of core–periphery analyses opened a period in which attention to development issues in geography became much more sustained. Between 1974 and 1983, for example, articles which addressed development issues rose to 16% of all articles in *Economic Geography* and 13% in the *Annals*, while articles on development in the more recently founded *Antipode* reached almost 40% (Corbridge, 1986, pp. 4–5).

Even with this more intensive theorization of development in the Global South and deployment of the spatial problematic, however, development geography remained more a theoretical borrower than a theoretical leader. By the mid-1970s, dependency approaches were already coming under increasing fire from Marxist scholars for fetishizing geographical relations and miscomprehending class issues, and were thus being forced into refinements that could take account of increasing complexity in the 'world-system' (Sheppard et al., 2009, pp. 81, 89–92), including the possibility of 'dependent development' in what had formerly been peripheral areas. Moreover, the 1970s had seen the emergence within development studies of important work on gender issues (Sheppard et al., 2009, pp. 92–94), an emphasis which was at that point absent in work by most development geographers.

By the late 1970s and early 1980s, a more fully fledged turn in the direction of Marxist theory was evident in the work of many development geographers (Slater, 1977), while others had taken note of the importance of world-systems theory (Taylor, 1981). Eventually, development geographers also paid greater attention to the claims about dependency put forward by the partisans of 'dependent development' approaches (Forbes, 1984; Corbridge, 1986), and relatively complex arguments about the interaction of 'external' and 'internal' factors began to appear in works on issues such as regional development (Gore, 1984) and urbanization (Armstrong and McGee, 1985).

Within development theory in general, however, the issues raised by both dependency theory and its Marxist critics had largely faded from view in the 1980s. For neoclassically oriented economists, the dramatic growth of East Asian newly industrialized countries (NICs) in the 1970s and 1980s both undermined claims of blocked development on the periphery and vindicated assertions that unfettered markets performed better than those in which the state intervened (Sheppard et al., 2009, pp. 97–104). These arguments were countered by the claims of an emerging 'neo-Weberian' school, which presented evidence for the important role of the state in guiding the economic growth of the Asian NICs (Glassman and Samatar, 1997).

In spite of the fact that theorization of Third World states by geographers has been limited (Glassman and Samatar, 1997; Glassman, 1999), emphasis on the political and economic role of the state was by no means foreign to development geography. Indeed, by the mid-1980s a number of development geographers had already begun to take up the theme of state activism in the East Asian growth story (Grice and Drakakis-Smith, 1985; Browett, 1986). Moreover, development geographers also foregrounded the spatial problematic in discussions of the state by highlighting state roles in creating and maintaining regional disparities within developing countries (Watts, 1983; Samatar, 1989; Slater, 1989).

Work on issues such as gender and development began to gain more attention in development geography by the end of the 1980s (e.g., Momsen and Townsend, 1987). These included analyses of the gendering of immigration processes (Radcliffe, 1986) and of the gendered environmental outcomes of development (Rocheleau, 1987).

By the 1980s and 1990s, geography as a field had begun to make what were arguably leading contributions to the formulation of theoretical positions surrounding contemporary development issues. To some extent, this was less a matter of geography as a field catching up with development studies than it was a matter of development studies coming around to some of the issues which are part of the spatial problematic – in particular, transnational geographic expansion of economic processes (neoliberal globalization), human–environment interactions, and difference and spatiality.

Yet, even as development geography and the rest of the social sciences began to increasingly speak a 'spatial' language, further permutations in the social sciences began to transform the ways development geographers worked and the ways they talked about spatiality. In particular, in the era of neoliberal globalization, and especially from the 1990s to the present, a combination of feminist theory, neo-Foucauldian influences, postcolonial theory, and postdevelopment approaches has generated new research agendas that in part build on the previous spatial problematic and in part transform it (Sheppard et al., 2009, pp. 104–112; Slater, 2004). The general move toward such 'post-prefixed' approaches has been enabled by a growing sense that in a post-Cold War world globalizing capitalist development defines the immediate future of virtually all countries. As such, development theory has tended to evolve past debates of the Cold War era that posed socialism as a short-term possibility within much of the Global South. Instead, a series of postdevelopment perspectives have emerged, calling into question more radically than had dependency, Marxist, or neo-Weberian perspectives the very project of development, whether in capitalist or any other form.

Lines of postdevelopmental research and theorization that extend to the present have generated much unresolved debate, including over some of the basic historical and theoretical contentions of the postdevelopmentalists (Cowen and Shenton, 1996; Mitchell, 2002) and the degree to which development can or should be opposed (Gidwani, 2008; Wainwright, 2009). More specifically, development geographies of the neoliberal globalization era have placed more firmly on the agenda issues such as the gendering and racialization of development (e.g., Perrault, 2003; Bakker and Silvey, 2008; Andolina et al., 2009), the imperial and statist violence that has been integral to actually existing development (e.g., Harvey, 2003; Gregory, 2004; Nevins, 2005; Retort, 2005), and the geographical imaginaries that are part of globalization and regionalization (e.g., Slater, 1997; Sidaway, 2002, 2012; Glassman, 2010). The spatial problematic has been enriched by the emergence of these issues within development geography, with debates in the field – for better or worse – becoming in some ways both more enlivening and less focused than in the earlier post-Cold War period.

Contemporary Themes in Development Geography

While modernization approaches had been generally optimistic about the prospects for capitalist development in developing countries, much of the literature by dependency theorists had been highly pessimistic. Since at least the 1980s, however, many development theorists have been inclined toward a more contextual approach that recognizes both possibilities for and limitations to capitalist development. In place of the earlier emphasis on either diffusion or blocked development, there is now much greater emphasis on the general geographical expansiveness of capital and the unevenness with which its expansion proceeds – at all scales from the global, transnational, and national to the subnational, local, and bodily. The important theoretical work of David Harvey (1982/2006; 2003) has enriched the conceptual foundations for analyses highlighting uneven internationalization of capital – analyses which have been carried forward by a variety of development geographers (see Smith, 1984/2008).

Much work on uneven development by geographers has focused on uneven development at the national scale, especially uneven economic growth between regions (Watts, 1983; Samatar, 1989; Slater, 1989; Park, 2003). The most basic point to emerge from such studies has been that capitalist development – whether or not it is relatively dynamic in a given context – occurs as the result of differential power relations that have concrete spatial expression. These differential power relations lie behind the spatial unevenness of capitalist development and tend to work at odds with efforts to create greater sociospatial equality in the development process. Indeed, in countries that have been relatively successful at 'late' industrialization, the production of disparity is sometimes accelerated rather than slowed (Glassman, 2004, 2010).

Directly related to the phenomenon of national unevenness in the development process are issues surrounding urbanization in developing countries. While it is less fashionable now than it once was to speak of 'over-urbanization,' there is still much emphasis on how regional disparities in growth relate to the preeminence of primate urban centers – these often being former centers of colonial administration and/or commercial centers of long standing. Instead of gradual equilibration of growth rates between these centers and outlying regions, capitalist development has generally increased the dominance of primate urban centers. Indeed, it has been suggested by development geographers studying Asia that spill over from expansion of primate urban centers has led to a historically unique form of extended metropolitan growth, which blurs preconceived boundaries between urban and rural, industry and agriculture (McGee, 1991).

At the same time, the explosive growth of particular urban centers in the context of global economic transformation has led to increasing investigation of the ways uneven development detaches the trajectories of urban centers from their 'hinterlands' while creating global networks of cities through which there is an intensified flow of money, goods, and information (Friedmann, 1986; Taylor, 2004). On this view, the spatial unevenness of development increasingly manifests itself as a bifurcation between the major nodes through which capital moves internationally (large urban centers) and much of the rest of the world, with nonurban areas and slums of the developing world being particularly marginalized (Davis, 2006). Thus, as many contemporary core–periphery theorists see the matter, in the era of neoliberal globalization the global core–periphery structure has been transformed from a global hierarchy of states shot through by global commodity chains (Wallerstein and Hopkins, 1986) to a global city network in which capitalist monopoly power is increasingly centered in networks of cities housing crucial advanced producer services (Brown et al., 2010). In this global city network, much of the rest of the world is seen as 'yoked' to this city network as a peripheral supplier of resources and labor (Taylor, 2007). In the neoliberal world of globalization, the ultimate expression of global uneven development is thus less the global hierarchy of states – though this still exists – than the relationship between dominant cities (and the social classes residing in them) and what Mike Davis calls the 'planet of slums' – the vast populations all over the world, still predominantly in the Global South, that increasingly face a dismal future of insecure informal sector employment, substandard housing, noxious living and working environments, social violence, and generally difficult, truncated lives (Davis, 2006).

Both the emphasis on networks of global cities and the emphasis on slum settlements can threaten a one-sided and monolithic vision of capitalist globalization, a vision contested by postcolonial geographers arguing for more attention to 'ordinary cities' (Robinson, 2006). Moreover, even with the transformations of the geographical imagination of development pursued by world systems and world cities theorists, to present the unevenness of capitalist development in too monolithic a fashion risks reification of the spatial dimensions of development at the expense of a spatially grounded analysis of social relations. Geographers have attempted to guard against such 'spatial fetishism' – that is, the view that geographical relations have their own independent dynamics, rather than being the spatial expressions of social processes – by foregrounding issues that include the spatial dynamics of class struggles and gender relations. Uneven development thus implies not only uneven development between places but uneven power relations and opportunities for groups of people, dependent upon such characteristics as their class, gender, race or ethnicity, sexual orientation, and age, with considerable variability in social outcomes, contingent on specific histories and contemporary social struggles (Hart, 2003; Roy, 2003).

Among development geographers, particular attention has been paid to the spatialization of disparity in the development process. For example, feminist geographers have examined how transformations in Mexico's accumulation process have involved breaking down the hegemony of the family wage-based, male-dominated, and Mexico City-centered labor regime while substituting a lower-wage and geographically more decentralized regime in which women are employed in much larger numbers, while being increasingly regarded as disposable (Cravey, 1998; Wright, 2006). They have also examined the migration of women to export processing zones, which have been the key to economic growth in newly industrializing countries of Southeast Asia, China, and Latin America (Chant and Radcliffe, 1992; Chant and McIlwain, 1995; Wright, 2006). Labor geographers have examined the

strengths and weaknesses of attempts to create various forms of solidarity between labor and other popular organizations in developed countries such as the USA, and less developed countries such as those of Latin America (Herod, 1995; Johns, 1998). Authors writing about 'new social movements' and 'popular development' (Brohman, 1996) have examined how such movements attempt to forge international linkages ('jumping scale') in order to strengthen their position (Cumbers et al., 2008). Geographers examining state power have noted both how it is transformed by processes such as 'globalization' and how it continues to play a crucial role in relation to various kinds of social struggles through which 'globalization' occurs (Agnew and Corbridge, 1995; Yeung, 1998; Glassman, 1999).

All of these types of analyses bring an explicitly geographical dimension to social critique of globalization. What is either implicit or explicit in such critique is an emphasis on the way general processes, such as capitalist development, can have different types of manifestations in different locations, because of the relationships between different social groups within and across those locations (Nagar et al., 2002). Thus, the study of development geographies requires balancing an adequately supple general theory with examination of the specifics of development in particular contexts. Theories of capitalist development must be able to explain why the features of capitalism which are posited as general can lead to different kinds of outcomes – e.g., 'late industrialization' in one setting and 'blocked development' in another; stagnant real wages in one setting and rising real wages in another; increasing marginalization of certain women workers in one setting and new opportunities for empowerment of women in another.

The variegated outcomes of global capitalist development include its varied environmental impacts. Within development geography, an important literature on issues of political ecology emerged in the 1990s and has since then taken up the task of theorizing environmental change in the context of globalization (Peet and Watts, 1996). Political ecology can be seen as combining a focus on details of local ecosystems and social structures with attention to global forces. In addition, political ecologists have shown a strong interest in what Peet and Watts (1996) term 'liberation ecologies' – varied struggles to transform environmental conditions in developing countries, which are often approached by political ecologists through post-prefixed conceptual frameworks, emphasizing the multiclass and frequently community-based forms of local environmental resistance (e.g., Tsing, 2004; Wolford, 2010). A number of political ecologists have brought gender and race into the center of the research agenda, highlighting, for example, the importance of gender-differentiated control over local and household resources to the economic and environmental outcomes of development projects, and the racialization of different forms of agricultural development (e.g., Carney, 1993, 2001). More generally, feminist political ecologists have noted how processes of transformation which are occurring in the global economy may have varied effects on women and men in specific localities, depending upon the social position in which they start and the sorts of resources to which they have (or are denied) access (Rocheleau et al., 1996).

Political ecologists have paid special attention to issues of food and agriculture. Michael Watts' study of uneven development and the food crisis in Nigeria (1983) helped bring the issue of food and access to it firmly onto the agenda, and subsequent research by development geographers has continued to analyze access to and control over agricultural resources (Samatar, 1989; Gidwani, 2008). Topics examined in relation to such issues of access and control include the impact of contract farming on local food production (Little and Watts, 1994), the impact of new agricultural technologies on poverty and food security (Yapa, 1993, 1996), and the ways varied global processes enable or disable forms of struggle, not only over resources but over the conceptualization of resources and social space (Wainwright, 2009), including its relationship to indigenous identities. Given the monumental social transformations underway in China, it is not surprising that a significant and robust literature has emerged charting varied transformations of land use in China, in both urban and rural settings (e.g., Lin, 2009; Hsing, 2010; Webber, 2012). Likewise, given the enormous importance of petroleum and other extractive industries to global capitalism, it is not surprising that such industries have begun to receive sustained and detailed attention from development geographers (e.g., Bebbington, 2012; Bridge and LeBillon, 2013).

Conclusion

The various but often overlapping and interconnected strands of research identified here, while they all exemplify the spatial problematic in development geography, may defeat any attempt at any simple synthesis – though attempts are made to present development geography as a unity in diversity (e.g., Sheppard et al., 2009). Such presentations of development geography's unity in diversity connect the traditions of political economy of development and political ecology with postmodern and postcolonial approaches to development studies. It is at the conjunction of these approaches, particularly as they address various issues surrounding neoliberal globalization, that much of the most interesting work is currently being conducted. In the twenty-first century, the centrality of globalization, uneven development, environmental challenges, and popular responses to these processes by diverse groups seems clear; and much of the specific research carried out by development geographers is related to this central problematic. At the same time, the pace and scale of global change itself makes attempts to predict where development theory in geography will head in the future a daunting task.

Abstract

Behavior genetics is the study of genetic and environmental influences on individual differences in behavior. Over the past decades, this rapidly evolving field of research has provided compelling evidence for substantial genetic contributions to all important domains of human behavior. Therefore, human development cannot be fully understood without comprehension of the logic of behavior genetics research and knowledge about its main findings. The present article will focus on the quantitative-genetic approach and primarily on twin studies constituting the bulk of the pertinent evidence. We will begin by describing the logic of twin studies and defining the major concepts of quantitative genetics such as heritability as well as shared and nonshared environmental effects. Furthermore, the assumptions underlying the classic twin designs as well as more recent methodological developments are surveyed and findings in the areas of ability and education with a focus on developmental behavioral genetics will be presented. One of the most important findings is that not only individual prerequisites of learning, such as intelligence, are highly heritable, but that this is also true for educational outcomes, such as school achievement. Further counterintuitive findings are that the influence of genes on behavior becomes stronger with increasing age and that it varies in accordance with socioeconomic status. In the final section, we discuss the common misconceptions about the implications of these findings for education.

Introduction

Behavior genetics, the study of genetic and environmental origins of individual differences in behavior, is an interdisciplinary area combining the behavioral sciences and genetics. Today's field of behavior genetics encompasses diverse research strategies – such as twin and adoption studies – called *quantitative genetics*, which investigate the relative importance of genetic and environmental influences, as well as strategies to identify specific genes associated with individual differences in behavior – such as allele association studies – called *molecular genetics* (Plomin et al., 2008). Behavior genetics is arguably one of the most rapidly evolving scientific fields today, characterized by a breathtaking pace of discoveries and methodological advances that continues to accelerate. A generation ago, it seemed that the outcome of the nature–nurture debate depended on the degree to which twin and adoption studies revealed substantial genetic contributions to important domains of human behavior. This research has yielded almost unanimous results indicating that individual differences in all behaviors are subject to genetic influence. It is now generally accepted that genetic influences on behavior are ubiquitous, so much so that Turkheimer (2000) summarized this fact as "the first law of behavior genetics". This general prevalence of genetic influences is of critical importance for our understanding that major sources of behavior lie in individual differences intrinsic to the individual. Therefore, it is a logical next step trying to identify specific genes that account for this genetic variance. However, despite marked advances in molecular biology and genetics during the past decade that have included techniques that make it possible to search the entire genome for genetic variants, which may be related to disease states or psychological traits (see also Strobel and Brocke, 2011), our knowledge of specific genes that are responsible for, and provide a sufficient explanation of, specific behavioral outcomes is rather limited (e.g., Johnson et al., 2011) and it seems unlikely "that most of the genes responsible for the heritability for any complex trait will be identified in the foreseeable future" (Haworth and Plomin, 2010: p. 784). The present article will therefore focus on the quantitative-genetic approach and primarily on twin studies constituting the bulk of the pertinent evidence, although we acknowledge adoption designs as alternative or complementary approaches, which are discussed in detail elsewhere (Plomin et al., 2008). We will begin by defining the major concepts of quantitative genetics and then summarize findings in the areas of ability and education with a focus on *developmental behavioral genetics*. This is the study of genetic and environmental influences on individual differences in behavioral development, and it combines a behavior-genetic approach with a developmental approach. A topic for developmental behavioral genetics that can be studied longitudinally as well as cross sectionally is how genetic and environmental influences are related to the age of the samples under study.

Concepts

Quantitative Behavior Genetics and the Classical Twin Method

The development of the twin method is usually ascribed to Galton (1876) although it is uncertain whether Galton was aware of the distinction between monozygotic (MZ) and dizygotic (DZ) twins (Rende et al., 1990). The classical twin study compares the phenotypic resemblances of identical or MZ and fraternal or DZ twins. MZ twins derive from the splitting of one fertilized zygote, and therefore they inherit identical genetic material. DZ twins develop from two separately fertilized eggs and are first-degree relatives: They share on

average 50% of the genes that differ among humans – as do full singleton siblings. It follows that a greater within-pair similarity in MZ compared to DZ twins suggests that genetic variance influences the trait under study. Comparing the phenotypic or observable resemblance of MZ and DZ twins for a trait or measure under study offers a first estimate of the extent to which the phenotypic variation of that trait reflects genetic variance. This is typically measured by using a statistic called heritability.

Heritability, Shared Environmental, and Nonshared Environmental Effects

Heritability is defined as the proportion of phenotypic differences among individuals that can be attributed to genetic differences in a particular population. The *heritability* (h^2) of the trait can be estimated by doubling the difference between MZ and DZ correlations, that is, $h^2 = 2(r_{MZ} - r_{DZ})$ (Falconer, 1960), with r_{MZ} and r_{DZ} as the correlations between MZ and DZ cotwins, respectively.

Shared environmental effects index the extent to which people are similar independently of shared genetic effects, because they share some environmental influence such as parental socioeconomic status. The proportion of the variance that is due to *shared environmental effects* (c^2) can be derived by calculating $c^2 = r_{MZ} - h^2$, because MZ similarity can be conceptualized as h^2 (similarity due to genetic influences) + c^2 (similarity due to shared environmental influences). Substituting $2(r_{MZ} - r_{DZ})$ for h^2 offers another way of calculating shared environmental effects, resulting in the formula $c^2 = 2r_{DZ} - r_{MZ}$. In other words, the presence of shared environmental influences on a certain trait is suggested if DZ twin similarity exceeds half the MZ twin similarity for that trait. A DZ twin correlation, which is less than half the MZ twin correlation, indicates the presence of nonadditive genetic effects being shared 100% by MZ twins but 25% or less by DZ twins. In contrast to additive genetic effects, which occur when the effects of alleles at a particular locus and across loci act independently of each other and thus additively, nonadditive genetic effects occur when the effects of alleles depend on the presence of other alleles either at the same locus (dominance) or at other loci (epistasis). Nonshared environmental effects (e^2) are all nongenetic sources of differences between family members. Contributing factors include having different peers, attending different classes, participating in different leisure activities, and receiving different parental treatment. Their combined effects can be estimated from $e^2 = r_{tt} - r_{MZ}$, where r_{tt} is the reliability of the measure. If $1 - r_{MZ}$ is used to estimate e^2 instead, the resulting nonshared environmental influences are confounded with measurement error.

For example, in studies of more than 10 000 MZ and DZ twin pairs on general cognitive ability (*g*), the average MZ correlation is 0.86, which is near the test–retest reliability of the measures, in contrast to the DZ correlation of 0.60 (Plomin and Spinath, 2004). On the basis of these data, application of the above formulae results in a heritability estimate of $h^2 = 0.52$, shared environmental estimate of $c^2 = 0.34$, and nonshared environmental influence/measurement error estimate of $e^2 = 0.14$. Thus, given that MZ and DZ twin correlations are available, this straightforward set of formulae can be used to derive estimates of genetic and environmental influences on any given trait. Instead of the more widespread Pearson product–moment correlation coefficient, twin similarity is typically calculated by using intraclass correlation ICC1.1 (Shrout and Fleiss, 1979) because the latter eliminates any bias due to nonrandom ordering of twins within pairs.

Requirements and Assumptions of the Twin Method

Interpretation of twin correlations in the described manner relies on a number of assumptions: the absence of assortative mating for the trait in question; the absence of G(enotype)–E(nvironment) correlation (rGE) and interaction (G × E); and the viability of the equal environments assumption (EEA). Each of these assumptions is addressed briefly below.

Assortative mating describes nonrandom mating that results in similarity or dissimilarity between spouses. If spouses are more similar than randomly paired couples and a trait shows genetic influences, their offspring show higher correlations due to increased genetic similarity resulting from the transmission of similar genes from both parents. Assortative mating can result from social stratification for similar traits, and thus from simple propinquity (people tend to select their spouses from those around them socially), and/or from active social selection, as when people of a given religious faith in a religiously mixed society select their spouses specifically from among those of their own faith. Assortative mating tends to be low for some psychological traits (e.g., personality), but can be substantial for others (e.g., intelligence, with average spouse correlations of about 0.40; Jensen, 1998). In twin studies, unrecognized assortative mating can result in underestimates of heritability, because it raises the DZ correlation but does not affect the MZ correlation, thus mimicking shared environmental influences.

Gene–environment correlation (rGE) describes the phenomenon that genetic propensities can be correlated with individual differences in experience. This occurs when either there is genetic control of exposure to environmental circumstances, or there is environmental control of gene frequency, or a third variable like parents' socioeconomic status shows accordant genetic and environmental effects.

Three kinds of gene–environment correlation are typically distinguished (Plomin et al., 2008). *Passive* correlation occurs when parenting practices that foster the development of heritable traits in children are correlated with those traits. The children need play no active role in the gene–environment correlation they experience. But parenting is clearly a reciprocal function: parents respond to what their children do and appear to need. *Evocative* gene–environment correlation expresses the extent to which parental responses (and those of anyone else in the child's environment) are tailored to traits that are genetically influenced in the children. And children make active choices about their activities, whether they involve other people or not. *Active* gene–environmental correlation takes place when people's selections of activities that relate to trait maintenance or development are themselves genetically influenced. The distinctions among these kinds of gene–environment correlation are not clear-cut. For example, parents may respond to children's active expression of interest in specific activities by giving them lessons in those activities, mixing

active and evocative gene–environment correlation. And parents with certain characteristics may be more likely than others to take their children to museums, but some of the children who have these experiences may learn much more from them than others, mixing passive and active gene–environment correlations (see also Spinath and Johnson, 2011). Research indicates that genetic factors often contribute substantially to measures of the environment, especially the family environment (Plomin, 1994). In the classic twin study, however, rGE is assumed to be zero.

Genotype–environment interaction ($G \times E$) is often conceptualized as the genetic control of sensitivity to the environment (Kendler and Eaves, 1986) or as environmental control of differential gene effects. Heritability that is conditional on environmental exposure can indicate the presence of $G \times E$. The classic twin study is based on the assumption that there is no $G \times E$.

The classic twin model is based on the assumed equality of pre- and post-natal environmental influences within the two types of twins. In other words, under the *equal environments assumption* we assume that environmentally caused similarity is roughly the same for both types of twins reared in the same family. Violations of the EEA because MZ twins experience more similar environments than DZ twins inflate estimates of genetic influences. The EEA has been tested in a number of studies. Even though MZ twins appeared to experience more similar environments than DZ twins, these differences did not seem to be responsible for the twins' differential similarity (Borkenau et al., 2002; Bouchard and Propping, 1993).

Advances: Beyond the Classic Twin Study

The comparison of intraclass correlations between MZ and DZ twins can be regarded as a reasonable first step in our understanding of the etiology of particular traits. This approach, however, cannot accommodate the effects of variations in the sizes of MZ and DZ samples, or mean or variance differences between types of twins. Nor can it accommodate the effect of gender on variances and covariances of opposite-sex DZ twins. To model genetic and environmental effects as the contribution of unmeasured (latent) variables to phenotypic differences, structural equation modeling (SEM) is required. Analyzing univariate data from MZ and DZ twins by means of SEM offers numerous advances over the mere use of correlations; these advances include a test of overall statistical fit of the model for the greater MZ twin compared to DZ twin similarity, tests of parsimonious submodels, maximum likelihood confidence intervals for each latent influence included in the model, and use of maximum likelihood estimates to incorporate information on participants with incomplete data. The most important strength of SEM, however, lies in its application to multivariate and multigroup data. During the last two decades, powerful models and programs to estimate these models efficiently have been developed (Neale et al., 1999). Recently, an even more flexible tool-kit was provided to the scientific community. OpenMx is a free and open source software for use with R that allows estimation of a wide variety of advanced multivariate statistical models (Boker et al., 2011; http://openmx.psyc.virginia.edu/). Extended twin designs, that is studies including relatives of twin pairs, and multivariate genetic analyses, that is the simultaneous analysis of correlated

Figure 1 (a) Partial path diagram for one twin demonstrating the incorporation of $G \times E$ in a univariate ACE model by partitioning genetic effects into a mean part, which is independent of the environment, and a part which is a linear function of the environment. (b) Partial path diagram for one twin depicting an extended $G \times E$ model allowing for gene–environment correlation (rGE). The moderator features twice in the model – as a dependent variable to be modeled as well as a moderator variable to define the paths to the trait. The main effect in the means model has been replaced with a path indicating shared genetic effects. The trait is now influenced by two sources of genetic influence: that which is shared with the moderator, and that which is not (common and unique paths a_C and a_U). A = additive genetic effects, C = shared environmental effects, E = nonshared environmental effects, M = environmental moderator variable, T = behavioral trait, μ = intercept. traits, are among the most important developments that go beyond the classic twin designs, yet still use the information inherently available in twins (Boomsma et al., 2002). Among the most exciting advances in quantitative behavior genetics is the possibility of analyzing Gene–Environment correlations (rGE) and Gene × Environment ($G \times E$) interactions within the framework of extended twin designs (e.g., Johnson et al., 2006; Purcell, 2002) and multigroup analyses (Hahn et al., 2012). Figure 1 illustrates how rGE and $G \times E$ can be incorporated in variance components twin-analyses.

Findings

Quantitative-Genetic Findings in the Domains of Ability and Education

Twin, adoption, and family studies have convincingly shown that individual differences not only in intelligence (for an overview, see Deary et al., 2006, 2009; Plomin et al., 2008) but

also in educational success (like school achievement and educational attainment) as well as in noncognitive predictors (e.g., personality) are driven by both genetic and environmental effects (Bouchard, & Loehlin, 2001; Johnson et al., 2008). There is now ample evidence that the heritability of intelligence shows a monotonous increase from childhood to adulthood (for a recent meta-analysis, see Bergen et al., 2007; see also Haworth et al., 2010). In addition, longitudinal behavior genetic studies have found evidence for genetic change (e.g., the onset of genetic effects which were not in effect at the previous measurement occasion) at two important developmental transitions: the transition from infancy to early childhood (marked by rapid language development) and the transition from early to middle childhood (around 7 years of age, marked by the start of formal schooling). A number of studies found genetic influence on facets of educational success like years of school attendance (Behrman et al., 1980; Behrman and Taubman, 1989), scores in specific school achievement tests (see Plomin et al., 2008), and broader measures of school achievement (Bartels et al., 2002; Johnson et al., 2005, 2006, 2007; Sacerdote, 2002). Only a handful of studies has included multiple cognitive and noncognitive predictors (intelligence, motivation, and personality) as well as an assessment of environmental and family influences in a genetically informative design. Johnson et al. (2005, 2006) found that about 70% of the variance of a school achievement measure (based on school grades) could be attributed to genetic influence of which 56% was shared with genetic influences on intelligence. In addition, engagement and motivation, family risk, conscientiousness, and disruptive behaviors also share genetic and environmental influences with intelligence and/or school achievement. Johnson et al. (2007), for instance, separated the relative influences of genetic and environmental effects on the covariance between individual traits (e.g., IQ), and family influences (e.g., parental expectations) on school grades. They found significant genetic influences common to parental variables and IQ as well common to parental variables and school grades, which indicate genetic generational transmission. Genetic and environmental contributions to the association between self-perceived ability (SPA) and school achievement (Greven et al., 2009) were studied recently and analyzed in a longitudinal genetic cross-lagged analysis (Luo et al., 2010). Results revealed that genetic influences contributed moderately to the association between earlier SPA and later school achievement and substantially to the association between earlier school achievement and later SPA.

Environmental Influences and Intellectual Development

Studies with a stronger focus on environmental factors influencing intellectual development have often targeted processes related to the family. Phenotypic research in this area has consistently shown a relationship between deprived family environments (e.g., low-quality home environment, poor nonmaternal care, etc.) and poor cognitive functioning (e.g., Feinstein and Bynner, 2004; NICHD Early Child Care Research Network, 2001; Petrill et al., 2004). More specifically, children from low-socioeconomic status (SES) groups are more likely to experience academic problems (Ellis and Bonin, 2003; Gutman et al., 2003; Jimerson et al., 2000). Beyond SES, researchers have begun to identify characteristics of the home and family environment (e.g., environmental confusion) that account for individual differences in cognitive functioning (van den Oord and Rowe, 1999; Hart et al., 2007).

Gene–Environment Correlation and Interaction

Family risk factors cluster as they do, in part, because they both have common causes and are mutually influential. Thus the roles of processes reflecting gene–environment (G–E) correlation and interaction (G × E) need to be examined (Johnson et al., 2006). For example, poor parental education and mental health or single parenthood may contribute directly to parental poverty, poor parental involvement and support, increasing the risk of low achievement in offspring of poor parents. These risk factors do occur systematically because they reflect characteristics of family members to some degree: low parental intelligence contributes directly to low parental education (Ceci and Williams, 1997), and certain personality traits contribute to poor parental mental health (e.g., Krueger et al., 2000) and to single parenthood (Jockin et al., 1996). The impact of genetically influenced risks can on the other hand be buffered by specific forms of social support (social capital) in the positive sense of social control (Shanahan et al., 2008), whereas restrictive educational policies (Heath et al., 1985) as well as poor social environments (Guo and Stearns, 2002) can severely limit the degree to which capabilities lead to intellectual performance and academic achievement. The study by Shanahan et al. (2008) is particularly noteworthy because it combines a candidate gene approach with the demonstration of a gene–environment correlation and interaction. Drawing on the National Longitudinal Study of Adolescent Health, Shanahan and colleagues studied the effects of social capital and the DRD2 dopamine receptor gene on educational continuation beyond secondary school. For boys, they found that DRD2 risk was associated with a decreased likelihood of school continuation. Parental socioeconomic status, high parental involvement in school, and a high-quality school compensated for this negative relationship, consistent with environmental contingency. However, the DRD2 risk allele was also less commonly observed in settings that were rich in social capital, suggesting that boys who were at genetic risk had a lower probability of benefitting from environmental compensation. Like all studies, this one clearly requires replication, but if it reports a robust phenomenon, it documents an important example of the kinds of gene–environment correlations and interactions that are likely to pervade the phenomena of interest to behavioral scientists, and the fusion of molecular and quantitative genetics that is going to be required to understand them.

Recent quantitative behavior genetic studies have also begun to include G × E interaction into their analyses. For example, the effect of the family environment on the heritability of intelligence was investigated in a couple of G × E interaction studies (Harden et al., 2007; Rowe et al., 1999; Turkheimer et al., 2003). Results suggest the importance of parental education and further socioeconomic indicators as

they modified the relative contribution of genetic and environmental effects on individual differences in intelligence.

Implications for Education

Behavioral genetic research and its findings are often perceived as a threat to the aims of education. This resentment is mostly based on misconceptions about what these findings mean and what genetically sensitive designs can tell us.

The most widespread misconception in this context is that heritability means that a characteristic is predetermined and fixed. To illustrate that this is not true, intelligence makes a good example. Although intelligence is substantially heritable within cohorts, massive gains in average IQ have been observed in industrialized countries since World War II (Flynn, 1987), most probably reflecting secular changes in environmental conditions. Heritability refers to differences between individuals, i.e., relative scores, not mean levels. Therefore, despite its heritability, a characteristic such as intelligence can undergo significant mean-level changes such as documented by Flynn (1987) and by meta-analyses on the effects of intelligence trainings (Klauer and Phye, 2008). In view of the distinction between rank order and mean level, heritability, and malleability no longer present a contradiction.

How can genetically sensitive designs inform education? It is counterintuitive, but behavioral genetic studies provide the best available evidence that environment does matter. This is the case because most studies aiming at demonstrating the importance of environmental factors neglect the fact that similarities between children and parents might in part be explained by shared genes, not only shared environments. Without controlling for the effects of shared genes, an association between parental behavior and children's outcomes cannot be interpreted as evidence of the effects of parental behavior. Nevertheless, the overwhelming majority of educational studies follow such a design.

There are many examples of important findings from studies with genetically sensitive designs that serve the aims of education. The fact that for intelligence heritability has been shown to increase over the life course is in line with the notion that education can achieve its best effects early in life (Bergen et al., 2007). However, it has often been shown that the effects of early interventions on intelligence do not transfer to later developmental stages (e.g., Schweinhart et al., 2005). The concepts of behavioral genetics, such as gene–environment correlation, can help to understand such disappointing findings. The older children and adolescents become, the more they create and choose their environments. According to the concept of active gene–environment correlation, this happens in such a way that the fit between environments and genetically influenced dispositions increases. For example, more intelligent children tend to be more successful in intellectually demanding tasks and thus tend to actively seek such challenges, whereas less intelligent children experience more failure in those tasks and therefore turn to less demanding activities. These insights make it clear that for long lasting changes, intervention programs need to continue beyond early childhood and should ideally take individual differences in a broader range of intervention-relevant variables on the side of the program participants into account.

Behavior genetics research can not only help to understand findings relevant to education but it can also show educational scientists and practitioners where to look for windows of malleability. To learn that shared environmental influences, such as parental educational styles, are probably less important than traditional educational theories claim, whereas nonshared environmental factors, such as peers, seem to be more important, might redirect the attention of researchers and educators interested in effective ways to optimize developmental processes.

Finally, behavioral genetic findings can guide educators in defining the goals of education. Because individual differences in educational prerequisites are substantially heritable, it is unrealistic that all learners will acquire the same level of educational outcomes. The aim of education cannot be to level out individual differences. The aim should rather be to enable each individual to make the best out of their potentials. A good school produces different educational outcomes for its students, but on a high level. Another consequence implied by behavior genetic findings is that the aim of realizing the potential of each student will not be reached by providing equal environments for all. Because of their individuality, learners need individualized environments and differential treatments to fully realize their potentials. That, of course, makes education not less important but more demanding.

Developmental Research across Cultures and Nations: Challenges, Biases, and Cautions

Abstract

Cultural models inform developmental pathways. Therefore the study of development requires the consideration of the cultural context, which, however, poses methodical challenges, since the research methods are mainly developed in the Western middle-class context. The present article describes those challenges exemplarily considering sampling, conceptions of knowledge and time, as well as situational demands and stimulus material. In the discussion, research strategies that combine naturalistic observations of everyday life and standardized psychological assessments are proposed.

Introduction

It is an interaction between biology and culture that constitutes human development (Keller, 2002, 2007). Culture selects and amplifies biological predispositions and thus affects developmental pathways. Therefore, the understanding of development requires cross-cultural research. However, the vast majority of studies on infant or early child development have been conducted in highly educated, industrialized, urban, Western middle-class communities, representing less than 5% of the world's population (Henrich et al., 2010). Usually, these samples of very privileged children, whose highly educated parents have time, resources, and motivation to carry their children to university laboratories, serve as the basis for claims about universal human behavior (Fernald, 2010).

This ethnocentrism in developmental research influences not only the selection of the research samples but also the research questions and methods (e.g., Bennis and Medin, 2010; Baumard and Sperber, 2010). Although constructs mostly evolved from Western psychology, a precondition of cross-cultural research is that the studied construct is incorporated in the psychological functioning in all included cultural groups. Even though this call for equivalence seems comprehensible, it is difficult to prove. While elaborated methods can statistically test structural or metric equivalence of scales, construct equivalence stays a theoretical assumption (Poortinga and van de Vijver, 2013).

From a methodical perspective, the general challenge of research with infants or young children arises from the fact that the participants are neither able to express their opinion verbally nor to react adequately to verbal requests. Therefore, researchers need to ask the caregivers, observe spontaneous behavior, or create situations and stimulus material, which prompt observable or measurable behavior providing information about the processes in question. As the field of infancy research has steadily grown since the 1950s and especially during the past decades, sophisticated research methods were developed in order to assess infant competencies. However, all research paradigms were developed in Western university laboratories reflecting the cultural model of psychological autonomy and the everyday experiences of infants and young children in highly educated Western middle-class families, therefore posing challenges in cross-cultural research.

The cultural model of psychological autonomy acts on the assumption that human behavior and experience is governed by personal preferences and independent mental states (Keller and Kärtner, 2013). Non-Western, traditional, subsistence-based communities constitute a context that differs tremendously from the typical Western research context. Usually, families in these traditional communities have only a low level of formal school education and limited access to other resources. The prototypical cultural model of this context is the model of hierarchical relatedness, which is based on an emphasis on communal goals, situational demands, and social role obligations (Keller and Kärtner, 2013). It is important to mention that the contrasting of the two cultural prototypes does not imply bipolarity and one-dimensionality of the concepts. These prototypes describe extreme forms that appear mutually exclusive, because the respective cultural model concordantly influences virtually all domains of behavior and experience. Of course, there are alternative combinations of the foci on autonomy and relatedness possible, since both constitute basic human needs. However, the comparison of these extreme, almost pure forms facilitates understanding the cultural influences on developmental processes.

Based on their ecocultural model, Keller and colleagues have argued and empirically documented that psychological autonomy and hierarchical relatedness organize caregivers' socialization strategies and thus infants' learning environments (Keller, 2007; Keller and Kärtner, 2013). The socialization goals of parents in Western middle-class contexts reflect the emphasis on psychological autonomy. Parents want their children to learn to express their individual preferences clearly and to develop personal talents, interests, and uniqueness. The main socialization goals of parents in rural traditional contexts can be described as obedience and respect to parents and elderly people and maintenance of social harmony. Pursuing these goals, parents prefer different interactional styles according to their cultural model (Keller, 2007; Keller et al., 2005a,b). Western middle-class parents set value on face-to-face interactions, object-related play, and elaborated talking about mental states. On the one hand, Western middle-class infants spend most of their time in exclusive dyadic interaction with

 http://dx.doi.org/10.1016/B978-0-08-097086-8.23159-0

their mothers or alone in their separate rooms. Infants in rural traditional families on the other hand, are cared for by multiple persons in their extended family system and are practically never alone. Most of the time, they experience close body contact and rhythmic body stimulations accompanied by rhythmic vocalizations.

In the following, it is discussed how these different cultural models and associated socialization goals and parenting behaviors challenge research routines in cross-cultural developmental research.

Sampling in Different Cultures

Sampling is always a demanding task in developmental research, because it is not only the Western educated middle-class that is overrepresented in psychological research, but within this group, college students are the most studied sample (Henrich et al., 2010). However, if one is interested in other populations, like infants, children, or older people, there will be several questions: How is the best way to get in contact with the study population? How should one approach them and convince them to take part in the study? What kind of reimbursement for study participation would be appropriate? Of course, there are no universal answers to these questions; they rather call for culture-sensitive solutions. Some cultural specifics will be illustrated using the example of infancy research.

To conduct an infant study in a Western middle-class context, one would probably first obtain a clearance from the university's or national ethics committee. Then the appropriate authority should be contacted to get access to the register of births in order to get a list of children of the relevant age. Alternatively, the potential participants could be approached via maternity or children's clinics, independent pediatricians, midwives, prenatal or baby classes, newspaper advertisements, or word of mouth. Once in contact, an individual appointment is arranged, informed consent is established, and the investigation can start. Afterward, the participants usually receive an individual allowance, even though most middle-class families participate in studies because of personal interest in the respective topic or the wish to support research in general.

However, in rural traditional contexts this is a different matter. Although an official ethical clearance would not be amiss, it is far from being sufficient for full acceptance of the project in the community. It is necessary to introduce the research team and the project to the local authorities or traditional rulers. They are the ones to decide what is going on in their villages, to represent the community's interest, i.e., to allow access to potential participants and demanding return service for the community. After reaching agreement with the village head, the actual recruitment process starts. Yet, in cultural contexts where birthdays do not play a major role in a child's life and chronological age is far less important than the social age, which is defined by assumed responsibility and social role obligations, sampling children of a certain age proves to be very difficult. If there are no birth registers at local health centers or clinic cards available, it is almost impossible to age a child reliably. Having found the right-age children it is not the mother (or parents) but rather the family head (usually an older male) who decides about the participation. Accordingly, the mothers or children are not in a position to cancel participation, in case they do not feel comfortable with the study requirements. Only high sensitivity of the researcher can secure to notice unexpressed escapes from the situation that would bias the results dramatically. Written consent as requested by ethical boards is unreasonable for illiterate participants.

Conceptions of Knowledge

Western psychology considers knowing as a mental activity of an individual. However, Greenfield (1997) argues that there is a different view of knowing as group process in many cultural communities. Referring to her experiences when interviewing Zinacantecan Maya girls and their mothers in Chiapas, Mexico, about weaving and embroidery, Greenfield describes the discrepancy between her perspective of individual participants with independent viewpoints and her participants' expectation of the more knowledgeable mothers answering for their daughters and answering being a cooperative effort to produce the most valid information (Greenfield, 1997). This view reflects the epistemological assumption of knowledge as collaborative construction (cf Duranti, 1988) and thus influences data collection procedures in several ways.

The author's experiences when assessing parental ethnotheories about infant care among rural Nso mothers point to the same direction. Many young mothers felt discomfort in the dyadic interview setting. They did not understand why other family members were excluded or at least requested not to intervene in the conversation. Furthermore, the restraint communication that is expected from the objective Western researcher was at odds with their expectation about appropriate communication. Thus, cooperative construction of knowledge was not permitted and diminished information might have been the consequence.

On the other hand, knowledge that is too obvious can also cause problems. Some interviewees felt embarrassed to answer questions about the best maternal care for infants. According to them, even young children know how to care for infants and thus, this is not worth talking about. Besides the discomfort in the interaction, this brings methodical problems when using rating scales. Asking for matters that everybody knows, i.e., shared knowledge within a cultural community, increases the probability of extreme responding and decreases the intracultural variation. These effects are usually seen as critical response styles and thus methodical artifacts. However, an alternative interpretation suggests understanding extreme response behavior and intracultural variation as meaningful aspects of cultural models (of parenting) (Lamm and Keller, 2007).

Affordances of Situations

Shweder (2010) argued that there is no research situation independent of the interpretation of the participant. Differential interpretation of experimental situations or assessment

settings by the participants might cause different behavior, even though the participants do not differ with respect to the psychological concept in question. Thus, it is impossible to interpret study results without knowing the situational interpretation of the participants (Rai and Fiske, 2010). However, infants or young children cannot tell how they experienced the situation or why they reacted in a certain way. Yet, detailed observations of infant behavior and emotional expressions can facilitate valid interpretations of results. This also implies looking at the infants' behavior from a holistic perspective rather than just assessing target behavior and analyzing the behavior of those infants who did not complete a task.

Using the example of working memory assessments with an A-non-B task illustrates the different situational interpretations of 9-month-old German middle-class and rural Nso infants (Lamm, 2013). Although the A-non-B task is an established method (e.g., Diamond, 1985), it did not work with the rural Nso infants. About two-thirds of the 9-month-old rural Nso babies did not search at all for the hidden objects (Lamm, 2013). The first possible explanation could be the absence of object permanence, which is a precondition for searching behavior. Given the scarce object experience of the Nso babies and the parental focus on relational developmental goals (Keller, 2007) this interpretation does not seem absurd. Possibly, the development of object permanence, i.e., an understanding that objects continue to exist even if they cannot be seen, heard, or touched (Piaget and Inhelder, 1987) is delayed compared to Western middle-class children. However, an alternative explanation for the not searching of the rural Nso infants is based on the situation itself. The hide-and-seek game might have been ambiguous for some Nso babies. Unless Western middle-class babies, who are familiar with this kind of peekaboo, the Nso babies occasionally seemed uncertain about the expected reaction. To them it was not always clear, whether they were allowed to fetch the toy that had been taken from them and hidden under the cloth. Even the question, where the object was, was not an explicit invitation to search for the object. These differences in the interpretation of the situation and the expected response between German middle-class and rural Nso infants reflect previous social experiences and cultural values and norms. Obedience and respect for elderly people are highly valued in the Nso socialization. Touching an object that is not mine or given to me marks a kind of disobedience, which caregivers would not authorize and which would be punished even in very young children.

Another example illustrating the effect of situational demands, even though not as much for interpretative reasons than mere familiarity with the situation, constitutes the application of the so-called mobile task in the rural Nso context (Graf et al., 2012). The mobile conjugate reinforcement task (e.g., Rovee-Collier and Cuevas, 2009) assesses contingency learning in infancy. Therefore, the baby is lying under a mobile, one leg of the baby is connected to the mobile, and it is observed whether the infant realizes the contingency between the leg kicking and the visible movement of the mobile. The cross-cultural comparison between three- and 6-month-old German middle-class and rural Nso infants using the mobile task revealed a remarkable difference in the spontaneous kicking activity during baseline phase, when the kicking had no effect on the mobile (Lamm, 2013; Graf et al., 2012). A considerable percentage of Nso infants (more than two-thirds at the age of 6 months) did not kick at all or showed an extremely low kicking activity. These infants had no chance to recognize the association between their movement and the movement of the mobile. Thus, the mobile conjugate reinforcement task is not considered an appropriate procedure to assess contingency learning in a sample of 6-month-old Nso infants. However, even those Nso infants, who showed at least a minimum of kicking behavior, kicked less than German middle-class infants. This difference in baseline activity is a methodical problem as it predicts the achievement of the learning criterion, which is following Rovee-Collier (1997) defined as a kick rate that exceeds the baseline rate by 1.5 times in 2 of 3 consecutive minutes during reinforcement. Across cultural groups, those infants who kicked less were more likely to reach the learning criterion, which implicates that more rural Nso infants were classified as learners (Graf et al., 2012). Yet, the interpretation of this result is anything but clear. It is not known whether the Nso infants learn the contingency more easily, because they kick less, or whether the German infants learn as well, but are not able to increase their high baseline kicking rate sufficiently to reach the learning criterion. Apparently, rural Nso and German middle-class infants start from different preconditions as regards the baseline activity level, which reflects the divergent everyday experiences of infants in these cultural contexts. German middle-class babies are used to the (half) lying position, as under the mobile. At the age of 3 months, they spend more than 50% of the day without body contact to anybody (Keller et al., 2005a,b) and consequently in a lying position. In contrast, 3-month-old Nso infants spend more than 80% of the time of a day in close body contact with another person, i.e., they are on the arm, back, or lap of somebody. If they are not in body contact, they are usually seated in plastic bowls or buckets padded with clothes. They are trained to sit from early on and at 6 months of age, virtually all Nso infants are able to sit without support (Lohaus et al., 2011). Thus, rural Nso infants are hardly ever lying and experience daily routines that are not conducive to kicking or independent leg movements. Hence, the task setting is not equally familiar to the infants from both cultural contexts. Lying and kicking are anything but typical activities for Nso babies. In order to avoid false conclusions on contingency learning, this has to be considered when interpreting the results.

A general characteristic of most assessment situations in infancy research is the dyadic nature. With respect to knowledge construction, the communicational implications of this dyadic isolation have already been discussed in the last section (cf *Conceptions of knowledge*). However, dyadic versus multiple person situations also influence the requested mode of attention. One-to-one situations between researcher and child are characterized by a researcher paying exclusive attention to the child and expecting the child to pay exclusive attention to the task. This constellation is atypical for children in rural traditional contexts. Cultures differ substantially with respect to norms and strategies for distributing caregiver's attention. In Western middle-class contexts, one of the major factors defining high-quality

parenting is the availability of a caregiver's undivided or exclusive attention within a dyadic context. Experts (cf sensitivity concept, Ainsworth et al., 1978) as well as mothers (Keller et al., 2005a,b) concordantly consider exclusive attention to an infant as absolutely essential to optimal child development. Mothers should be completely involved with their infants, see the world from their infants' point of view, and respond even to their infants' most subtle and understated cues, which is not possible without directing full and exclusive attention toward the infant. Despite the popularity of this view in Western middle-class contexts, in most of the world's child-rearing contexts, caregiving is conceptualized as a co-occurring activity (Saraswathi, 1994). Exclusive attention is a resource that caregivers in rural subsistence-based communities cannot afford to provide to large degrees. These caregivers provide their infants with constant physical proximity, while sharing their attention and engaging in extradyadic activities like household or subsistence work at the same time, thus contributing to family sustenance. But the mode of attention is not just a question of workload. Awarding exclusive attention encourages the development of a concept of self as a distinct individual and unique agent, while the shared attentional pattern supports the development of close social relations and the experience of being a coagent in a communicative system (Keller, 2007). Thus, the experience of exclusive attention of an adult in the dyadic research situation is unfamiliar, if not unsettling for children in rural traditional contexts. Many children in those contexts react with extreme shyness to this exceptional situation. Moreover, a cultural community's normative style of attention management is also acquired very early in life (Chavajay and Rogoff, 1999; Rogoff et al., 1993). Guatemalan Mayan toddlers from San Pedro showed remarkable ability to attend to several events simultaneously, for example, working with their caregiver on a task while monitoring another ongoing conversation, whereas Euro-American toddlers from Salt Lake City mostly focused on one event at a time, alternating exclusive attention between different events (Rogoff et al., 1993). Sibling caregivers from a rural Nso community in Northwest Cameroon also preferred a co-occurring care strategy (Lamm, 2008). In interviews, the 4- to 8-year-old Nso children mentioned the importance of accomplishing household tasks (e.g., fetching water or firewood) or the wish to play with their friends while caring for their infant siblings. Hence, the expectation of exclusive attention toward the test is also biased. The exclusion of possible distracting factors from the research situation reflects the Western middle-class idea of best possible results with exclusive focus. However, there is no empirical evidence that this presupposition holds true for children in rural traditional contexts. There are reasonable doubts based on the observation that rural Nso infants showed higher imitation rates when tested outside the laboratory room on a green area in front of the local health center as compared to the controlled laboratory setting (Teiser, 2010). Yet, it is too early for a clear conclusion and there is more empirical work on the effects of research settings needed, since the inside and outside testing differed in several other aspects (e.g., sitting position).

Affordances of Materials

Besides translation, adaptations of test materials and stimuli are the most obvious challenges in cross-cultural developmental research. There are several reports on the influence of familiarity with test materials on test results. Serpell (1979) observed considerable cultural differences in pattern reproduction as a function of test material: whereas Zambian children showed much better reproduction skills in the medium of wire modeling, British children performed better when reproducing the patterns by drawing. Yet, there were no group differences concerning the performances in the clay modeling task. Comparable experiences were reported from the Zambian Early Childhood Development Project (Fink et al., 2012) applying the Pattern Reasoning subscale of the Kaufman Assessment Battery for Children (Kaufman and Kaufman, 2004). During piloting it was noticed that Zambian preschoolers struggled to recognize the patterns. Based on the assumption that minor experience with things drawn on paper had complicated the tasks for them, an object-based version of the reasoning test was developed. The same items displayed through objects rather than printed on paper were much easier for the Zambian preschoolers. Thus, they were able to see the patterns, if they were presented in three-dimensional format and scored higher in the Tactile Pattern Reasoning scale in comparison to the Kaufman Pattern Reasoning scale (Fink et al., 2012). A third example for the effect of test material on test results comes from a study with Zinacantecan Maya children (Greenfield and Childs, 1977). These participants without or with very little school experience did not succeed in continuing weaving patterns correctly when they were drawn on paper. However, they were able to continue weaving patterns constructed with colored sticks in a wooden frame.

With respect to stimuli the necessity for adaptations to cultural contexts has been generally accepted. Malda et al. (2008) proposed a systematization of adaptation processes related to cognitive tests. They distinguished five types of adaptations that they consider sufficient to make cognitive instruments adequate to new cultural contexts: construct-driven adaptations reflect different definitions of psychological concepts across cultures; language-driven adaptations are necessary in the case of structural differences between languages or unavailability of semantically equivalent words across languages; culture-driven adaptations arise from cultural differences with respect to norms, values, customs, or practices; theory-driven adaptations describe modifications that are needed for theoretical reasons; and familiarity/recognizability-driven adaptations are caused by diverging familiarity with item characteristics or stimulus materials (Malda et al., 2008).

However, even visual stimuli that have been considered universally relevant provoke culturally different reactions. Pictures of human faces constitute preferred visual stimuli for infants, which was interpreted as evolutionary adaption (Keller, 2000). They caused the best and earliest memory performances, especially if the person was highly socially relevant and familiar (Bushnell, 2001). Therefore, they are highly qualified for studying processes of learning and memory in infancy. Nevertheless, the use of face stimuli from

the respective cultural context in a study on visual habituation revealed that rural Nso and German middle-class infants perceive different affordances in pictures of human faces. The Nso infants seemed much more animated to initiate an interaction with the faces than the German infants (Lamm, 2013). They smiled, vocalized, or tried to touch the face in order to get in contact. Additionally, Nso infants looked longer at the faces before achieving the habituation criterion. Yet, this difference in the total habituation time is not necessarily reflective of different information processing speed. In consequence of unsuccessful attempts to initiate social interaction infants reacted with frustration and crying causing dropouts from the study. Reasons for the different interpretations of the stimuli might be manifold. The rural Nso infants are not as used to the two-dimensional world of pictures as German middle-class infants. Therefore, they might have misinterpreted the pictures as real persons. Furthermore, Nso babies experience face-to-face positions and direct eye contact in mother–infant interaction less frequently than German middle-class babies (Keller, 2007). However, the photographs used as stimuli showed young women directly looking into the camera. Thus, the quasieye contact of the stimuli faces paired with the not reacting to social approaches might have confused, scared, or distracted the Nso infants from effective information processing.

Conceptions of Time

The pace of life differs tremendously across cultural contexts. What travelers experience and report frequently is reflected in prejudices (e.g., German punctuality or Mediterranean life-style), but has also been assessed systematically. Based on observations of three indicators (walking speed, work speed, and accuracy of public clocks) in 31 countries around the world, Levine and Norenzayan (1999) found that the pace of life was significantly faster in colder climates, economically productive countries, and in individualistic cultures. Thus, the pace of life is intertwined with different aspects of the ecocultural context as well as cultural norms and values. Accordingly, these pace differences influence and complicate cross-cultural psychological assessments.

To begin with, differences in pace of life result in organizational difficulties. It is challenging for a research team as well as in contact with study participants if one person is used to follow a tight schedule and fixed appointments and the other one does not even have a clock. Many Westerners name it among their first lessons from Africa that a great deal of the time is spent waiting. However, cultural openness, respectfulness, and reflection of those differences can resolve initial communicational difficulties. In the author's research team in the Northwestern grassfields of Cameroon, for instance, it has become a running gag to ask for each appointment whether it is set in white men's time or black men's time.

More serious than these anecdotes of intercultural communication is the question of time limits within test items or psychological assessments. Considering the described differences in pace of life or local observations that children are not trained to manage their time or perform quickly, some researchers relax original time limits of tests when using them in rural, non-Western contexts (e.g., Malda et al., 2008). Yet, this practice is problematic. It appears absolutely reasonable at first glance, but there is no conversion factor between different tracks of time. It is an arbitrary decision of the researcher to consider different time limits in different contexts equivalent. Not enough is known about cultural influences on information processing speed. The developing field of cultural neuroscience demonstrates that cultural experiences modify neurocognitive connectivity (Kitayama and Uskul, 2011). Thus, cultural differences in information processing speed might be reflective of experienced differences in the pace of everyday life. However, observed differences in the working speed might also be biases resulting from different familiarity with materials and settings.

Conclusion

In this article, it was argued that the only way to understand developmental processes implies the consideration of the ecocultural context. Systematic assessments and observations in divergent contexts are essential to gain insight into the interplay between biology and culture that constitutes development (Keller, 2002). However, cross-cultural developmental research turns out to be a great methodical challenge. Mostly, research constructs and assessment methods have been developed in Western university laboratories and are adapted to the highly educated, urban, Western, middle-class context. This bias becomes obvious in research questions, recruitment procedures, as well as the design of research materials and situations. There is no culture-free stimulus constellation and accordingly no culture-free test. Social conventions and cultural routines interfere with expected response behavior and familiarity with the materials and test situation influence achievement in a test. Hence, the development of methods and test procedures that are adequate in different cultural contexts is very demanding. The intended goal that a test reveals equivalent scores for members of different populations given the same skill (culture-fair test) has been proven untenable (e.g., Rosselli and Ardila, 2003). Hence, the efforts aim at reducing the cultural bias as far as possible (culture-reduced tests) and alternatively controlling the bias statistically (Poortinga, 1995). Throughout this article several examples of challenges in cross-cultural developmental research have been discussed. Even though the answers to these problems must always be culture-specific, general suggestions for culture-sensitive methods are derived from these examples. The basic prerequisite for cross-cultural research is the reflection of the own cultural values and norms as well as openness to experiences and a multicultural team. Methodically, psychologists can seek inspiration from ethnography. Field observations, detailed interviews, and participating in cultural routines give necessary information in order to adapt a psychological assessment instrument to a new cultural environment or develop a new instrument for the use in different cultural groups. This approach will help to overcome the ethnocentric bias in developmental research and increase the knowledge about cultural pathways of development.

Abstract

Dewey's work provides the foundation for a framework for social thought. Participatory democracy aims at 'the great community,' liberating the capabilities of each individual to promote the common good and thus improve on the quality of experience through application of intelligence to practice. Intelligence is the grasp of possibilities in a situation at hand. Democracy is contingent upon education, and education at its best is modeled for democracy ('embryonic society'). Philosophy, once it turns away from the futile quest for certainty, is seeking principles to solve the problems of men, and may be understood as education in a generic state. Dewey sought to expose dualisms as results of faulty thinking. Dewey's studies of various fields and disciplines are all contributions to the foundation of a framework for social life that facilitates the liberation of human potential. Against the separation of experience and dualistic views, he promotes the unifying moments in experience and the resolution of dualism; against concepts of certain truth and the eternal, he emphasizes the contingent and the present in the situation at hand; instead of the closed-down (e.g., the 'law of the laws of history') and shut-off, he points to the continuous and the transactional; against reifications of language and reason, he demonstrates their instrumentality; and instead of leaning to romantic pessimism, he puts a premium on cautious optimism in matters concerning human beings and the universe.

Biography

John Dewey was born in Burlington, Vermont, on 20 October 1859. By the time of his death (1 June 1952 in New York City), he was regarded by many as America's foremost philosopher. During his boyhood and youth in Vermont, Dewey had been an average pupil. In 1864, Dewey's mother moved with her four boys to Northern Virginia to be close to her husband, a quartermaster with the Union army during the civil war. They did not return to Vermont before 1867, and John as a young boy saw the carnage that war brings.

As a student at the University of Vermont in Burlington, he found a mentor, H. A. P. Torrey, who nourished his interest in philosophy. After graduation in 1879, Dewey spent 2 years teaching at the high school at South Oil City in Pennsylvania, and for one year taught at an elementary school in a small town in Vermont. He continued studying philosophy in private tutorial, and in 1882, enrolled at Johns Hopkins University in Baltimore. There, he gravitated quickly to G. S. Morris, a neo-Hegelian. Hegel's ideas had a liberating effect on Dewey's thought. The religious teachings that he was brought up with were transformed into the Hegelian view of cultural institutions as agents of an objective mind that through them shapes the mental life of individuals. Morris let Dewey teach his undergraduate class, secured a fellowship for him, and offered him a position as instructor at the University of Michigan at Ann Arbor where he had moved in 1884, the year of Dewey's PhD exam. During the following decade, Dewey stayed at the University of Michigan (except for 1888, the year spent at the University of Minnesota), where he was promoted to full professor, and wrote articles on psychology and ethics. In 1886, he married Alice Chipman, a strong personality with a secular humanist background. A formative influence – next to Morris' and to that of William James that mainly came by correspondence – was his friendship with G. H. Mead.

The exchange began in Ann Arbor and continued during the decade in Chicago, lasting until Mead's death in 1931. Mead's scholarship in physiology surpassed that of Dewey, and Mead's concept of psychology – based on a view of the organism that is interacting with its environment – was integrated by Dewey into his own transactional theory.

He accepted the offer to head the department of Philosophy, Psychology, and Pedagogy at the University of Chicago in 1894. The city of Chicago, teeming with European immigrants, full of destitute people as well as of people of means and goodwill, appeared to Dewey like one big social experiment. He worked closely with Jane Addams of Hull House, a social settlement; with Ella Flagg Young, District Superintendent of Chicago Schools; and with Francis Parker, principal of the Cook County Teachers' Training School. In 1896, at the request of parents who were willing to pay for most of the school's maintenance, he founded the Laboratory School that quickly became known as the Dewey School. The school's curriculum centered on 'occupations' that engaged pupils' minds and hands in activities such as sewing, weaving, cooking, building, growing corn, etc. A debate society complemented the syllabus for fifth- and sixth-graders. What made the school unique was not so much the emphasis upon the priority of the manual to the conceptual as the attempt to realize the idea of school as a community, in which both teachers and students were stakeholders.

Dewey's book *School and Society* (1899) – probably his most widely read book, with translations into a dozen languages – consists of talks he gave to raise money for the Laboratory School. In 1897, he had published a brief text, *My Pedagogic Creed*, that not only reflects his idea of the Laboratory School but holds much of his later more explicit writing on education in a nutshell.

Dewey's time in Chicago came to an abrupt end in 1904 when the University's president merged the Laboratory School with the Chicago Institute for Teacher Training, dismissing Dewey's school's teachers and his wife, who acted as principal, without prior notice or consultation with Dewey. He resigned immediately and found the position as professor of philosophy

at New York's Columbia University that he would hold from 1904 through his retirement in 1930, until his final resignation of all duties in 1939, at age 80.

Courses he had taught in Chicago were published in New York (*How we Think*, 1910; *Human Nature and Conduct*, 1922), and his major work on philosophy of education, *Democracy and Education* (1916) is a fruit of Dewey's involvement with schools and philosophy of education in Chicago.

In New York, Dewey was engaged with philosophy at Columbia and education at Teachers' College, and quickly he became involved in various political activities, not only as president of the American Association of University Professors and functions in the American Federation of Teachers, but also as leading contributor to *The Republic*, a magazine promoting liberal views, and as president of the People's Lobby and Chairman of the League for Independent Political Action. His travels and consultant activities in Japan (1919), China (1919–21), Turkey (1924), and Mexico (1926) extended his influence, and a series of lectures on a variety of topics resulted in major publications (Tokyo University 1919: *Reconstruction in Philosophy*; Carus lectures at Columbia 1923: *Experience and Nature;* Gifford lectures in Edinburgh 1929: *The Quest for Certainty*; Terry lectures at Yale 1934: *A Common Faith*).

John and Alice Dewey had six children, three boys, one of whom had died in 1895 on a sojourn in Italy, and three girls. In 1904, on their second trip to Europe, another boy died, and even though the Deweys adopted later, on that same tour, an Italian orphan who was eight years old like their lost son, they never came to accept these deaths.

Alice died after long illness in 1927; John Dewey was married again in 1946, at age 87, to Roberta Grant, and the couple adopted two children. In 1949, when he was 90 years old, Dewey published a book that he had written together with Arthur Bentley, *Knowing and the Known*, a study in epistemology.

Experience the Connecting Agent of Dewey's Life and Work

One of the more unusual features for a philosopher's biography is the close connection between Dewey's intellectual and actual life.

In politics, he tried his hand at founding a third party, at editing a newspaper devoted to 'thought news,' and at heading the Outlawry of War Movement ('That war be outlawed and declared a crime'). In his 50s and 60s, he traveled widely not only to spread his ideas, but also to help install systems of education in Turkey, Mexico, the Soviet Union; his sojourn in China lasted over two years. At age 78, he chaired the committee to investigate Leon Trotsky (an investigation at Trotsky's own request, in Mexico, into accusations by Stalin's courts in Moscow).

Looking back at 80, he wrote: "I reached fairly early in the growth of my ideas a belief in the intimate and indissoluble connection of means used and ends reached. I doubt if the force of the idea in the theory of social action would have come home to me without my experience in social and political movements, culminating in events associated with my membership in the Trotsky Inquiry Commission" (Jane Dewey, 1939).

As for education, having been a schoolteacher himself and having run the Laboratory School in Chicago, he points to the interaction between thoughts and actions: "The idea that lay back of my educational undertaking was a rather abstract one of the relation of knowledge and action. My school work translated this into a much more vital form" (Jane Dewey, 1939).

In the field of aesthetics and the fine arts, he had worked with Albert C. Barnes, the millionaire collector who befriended him and introduced him to the art of French postimpressionism; Dewey dedicated his book *Art as Experience* (1934) to him.

As for metaphysics, his concept of unity of the ideal and the actual that he named 'God' (*A Common Faith*) appears to have been backed by personal experience. During his sojourn as a young man in South Oil City, he had experienced a mystic oneness with the universe, and he would later declare: "I've never had any doubts since then, nor any beliefs. To me faith means not worrying ..." (Dykhuizen, 1973).

His first years as a young instructor at the University of Michigan in Ann Arbor had impressed on him the actual attainability of a cooperative community and the experience of personal growth within a democratic atmosphere, with encouragement of freedom and individual responsibility, and the immediate acceptance as an adult responsible member of the faculty. This experience may well have contributed to the formulation of his later visionary concept, presented in *The Public and Its Problems* (1927), of democracy as 'the great community.'

He himself summed up the mutual enforcement of idea and action throughout his experience in the autobiographical notes that he added to his daughter Jane's account of his life: "My belief in the office of intelligence as a continuously reconstructive agency is at least a faithful report of my own life and experience" (Jane Dewey, 1939).

Contribution

The upshot of Dewey's work can be described as the subordination of philosophy to life, a contribution to the project of intellectualization of practice. Since intelligence – the assessment of the possibilities inherent in a given situation – is a tool for the solution of practical problems, Dewey referred to his brand of pragmatism as 'instrumentalism': like the wings of a bird and the fins of a fish, human intelligence is an instrument for survival, but unlike the other creatures' physical features, the human mind is capable through the powers of community to promote life's quality itself, not unlike a process of evolution directed by intelligent action.

One of the most obvious principles in Dewey's philosophy is his exposure of dualisms as artificial alternatives that have become barriers to the kind of intelligence needed to promote the process of experience, e.g., the separation between science and morals appeared scandalous to him, a roadblock on the path to progressive application of intelligence. The method of scientific inquiry developed and employed successfully in modern times provides a model

for inquiry into social affairs to the degree that it is an application of reason against that of myth; analogously, intelligence must be applied in the social realm to develop a methodology for the resolution of the problems of men and to facilitate social reconstruction.

His dictum, that philosophers should turn away from the problems of philosophy and instead should turn to the problems of men, is another way of saying that traditional philosophy is concerned with questions that result from views framed in terms of alternatives which do not relate. As he states in an essay, *The Influence of Darwinism on Philosophy* (1909): "But in fact intellectual progress usually occurs through sheer abandonment of questions together with both of the alternatives they assume – an abandonment that results from their decreasing vitality and a change of urgent interest. We do not solve them: we get over them. Old questions are solved by disappearing, evaporating, while new questions corresponding to the new attitude of endeavor and preference take their place" (Middle Works 1973–83).

With regard to politics, Dewey maintained that the majority of men and women could and should become active participants in the decision-making processes that govern and shape their lives. He urged the development of a society that facilitates individual growth through participation in community life. Integration of self-realization and the social to form a common good is the major ethical postulate entwined with such an instrumentalization of the political. In *The Public and Its Problems* (1927), Dewey answered an analysis of the political situation in the USA in the years after World War II by Walter Lippmann, *The Phantom Public* (1925). Lippmann, a democratic realist, had shown that self-government and the idea of participatory democracy fell short of the reality of a population largely manipulated by propaganda, and he proposed the establishment of an elite ruling class to identify and serve the public interest. Dewey, while accepting the factuality of Lippman's analysis, did not subscribe to his proposal, but suggested instead the continued pursuit of the idea of a great community, especially through the means of education. His idea of the fullest possible liberation of the potentials of human experience allowed for no other social framework than that of participatory democracy. And for Dewey, the school as the 'church of democracy' is to provide the actual experience for achieving the 'great community' through its model as 'embryonic society.'

Probably, Dewey is known best for his contributions to educational thought. At the core of his philosophy of education is the concept of experience as an ongoing process with no externally identifiable aim. " ... education is a constant reorganizing or reconstructing of experience. It has all the time an immediate end, and so far as activity is educative, it reaches that end – the direct transformation of the quality of experience" (*Democracy and Education* 1916, Middle Works 1973–83). This concept was opposed to teleological concepts of education dominant in countries with an idealistically inclined tradition such as Germany or Japan, and at the same time provided the foundation for an interchange of participatory democracy and education as its exercise in embryonic form.

In *Experience and Education* (1938), Dewey emphasizes the need for a theory of education. Such theory is not a system or an application of static principles. It is entirely subservient to practice and should, in Dewey's words, be 'a light to the eyes and a lamp for the feet'; it might be described as a framework to facilitate a plan of action, or as a set of principles to interpret an experience's educational function.

Dewey elaborates two such principles of experience, that of continuity and that of interaction. He reminds educators to avoid the opposite pitfalls of overindulging children and of subjecting them entirely to external demands. Proponents of progressive education who promoted a child-centered approach had claimed Dewey as provider of the philosophical foundation for their sentiment, and W. H. Kilpatrick, an influential representative of that school, had declared the project method as Dewey's brainchild. But Dewey, while sympathetic to the idea of a participatory approach to education, would not want to see the curriculum content in terms of knowledge and competence buried underneath project-learning for its own sake. Continuity of experience, as he explained in 1938, requested the educator to transfer 'the vested capital of civilization': "The mature person, to put it in moral terms, has no right to withhold from the young on given occasions whatever capacity for sympathetic understanding his own experience has given him" (*Experience and Education*, Later Works 1981–91).

In *The Quest for Certainty* (1929), Dewey gives an account of cultural history that exposes the tradition of bad metaphysics in philosophy which seeks to establish a realm of certainty protected from the precariousness of human experience in a world of unavoidable uncertainty. While early religion attempted an alignment with the powers of destiny, philosophy – its inheritor – sought access to knowledge of the immutable, to the certainty provided by everlasting values and principles. Both religion and philosophy distinguished between skills and technical knowledge that eased the circumstances of everyday existence, and the superior knowledge connected to the higher order of absolute certainty in terms of truth, goodness, and beauty. The sciences that developed in the seventeenth century effectively replaced the qualitative view of nature with one describing it in terms of mathematical relationships. But instead of using that knowledge as an instrument in the service of liberating experience, scientists engaged in a quest for certainty on their own by redescribing reality in scientific terms, as if 'the findings of science are a disclosure of the inherent properties of the ultimate real' (*The Quest for Certainty*, Later Works 1981–91). Thereby, another dualism was generated: that between scientific procedure with the resulting quantitative description of relationships in nature, and that of the appreciation of qualities and values in experience. Dewey demonstrated how these dualisms dissolve as one turns away from the fixation on certainty in the name of reason and turns instead to intelligence as a means of assessing the possibilities inherent to a situation.

With *The Quest for Certainty*, Dewey aimed at a destruction of the history of philosophy in order to gain plausibility for democracy as the social arrangement with the greatest potentials for the full realization of society's capacities.

In *Art as Experience* (1934), Dewey stresses the continuity of all experience. The aesthetic is that part of experience that is identical with the form that separates an experience from the

ongoing flow of ordinary experience. It is of a satisfying quality for its consistent movement toward an intended end, which makes it self-sufficient and lifts it out of the stream of the ordinary, at the same time. An agreeable meal, an intelligent conversation, a talk professionally delivered, a well-conducted concert, a well-played game, etc. all qualify as an experience. As for art, the artist clarifies and intensifies an object's traits in such a way that a new experience results. He does so in a process that requires his attention to the medium he is working with, and the beholder of the finished work appreciates it only to the degree that he goes through the same processes that the artist went through when making the object. By describing art this way, by identifying the aesthetic as part of experience accessible to all, Dewey claims that the removal of the arts from the ordinary lives of the common people, its relegation to museums and to private collections of the wealthy has to be understood as symptomatic of the dualism that separates the aesthetic from the quotidian and is at the roots of the divisions of society.

Like the aesthetic, the religious offers an aspect of consummatory experience. Dewey had hinted in the final chapter of *Reconstruction in Philosophy* (1920) at a 'natural piety' that transcends the denominational and liberates the potentials of religious belief. In 1934, he delivered a series of lectures to extend and clarify his position, which were published under the title *A Common Faith*. He draws a distinction between the religious as disposition and religions as sets of rituals and dogmatic beliefs; he shows the realm of the religious to be the kind of belief that is not in competition with the kind of knowledge achieved through application of research and reason; organized religion, however, has interfered with the progressive expansion of knowledge. Dewey sketches the contour of a natural piety that takes humans to be part of nature and seeks its cooperation not without a just and dignified attitude. Experience of the religious culminates in the unification of the ideal and the actual, i.e., the realization of our most inclusive moral convictions in a given situation, through which an all-pervasive unity may be glimpsed momentarily that aligns human purpose and nature.

Dewey's studies of various fields are all contributions to the foundation of a framework for social life that facilitates the liberation of human potential. Against the separation of experience and dualistic views, he promotes the unifying moments in experience and the resolution of dualism; against concepts of certain truth and the eternal, he emphasizes the contingent and the present in the situation at hand; instead of the closed-down (e.g., Marxist 'law of the laws of history') and shut-off, he points out the continuous and the transactional; against reifications of language and reason, he demonstrates their instrumentality; and instead of leaning to romantic pessimism, he puts a premium on cautious optimism in matters concerning human beings and the universe.

Relevance for Contemporary Social Sciences

A renewed interest in Dewey is indicated by the number of doctoral dissertations, which doubled during the 1990s from an average seven at US universities in the early years to an average 15 for each of the later years. At the same time, the tone of studies on Dewey appears to have changed. An observation that might be symptomatic: Westbrook (1991) follows Dewey for the most part, but is still critical of his emphasis on education to reach the goal of participatory democracy; Eldridge (1998) attacks Rorty for misreading Dewey on scientific method, Niebuhr for misconstruing Dewey's metaphysics, and Westbrook for prioritizing political action over cultural development.

The explanation of Russel's and Horkheimer's reproach of Dewey's pragmatism as curious misunderstanding has become a common feature in the literature of the 1990s; the fierce Marxist–Leninist critique of Dewey's philosophy during the Soviet era is no longer an issue, other than a footnote, and the neoThomist repudiation of Dewey's secular philosophy is no longer even mentioned.

At the same time, several tendencies in the development of philosophy have helped facilitate a renewed interest in Dewey's philosophy. The rejection of 'great tales' in French postmodernist philosophy, the promotion of pluralistic views by proponents of constructivism, has exposed the untenability of philosophy's claim of a relationship with the immutable, for their part. One of the most influential thinkers of the 1980s and 1990s, Richard Rorty, has combined these sentiments and applied them in his reformulation of the contributions of philosophy. His *Philosophy and the Mirror of Nature* (1979) can be read as mirroring Dewey's *Quest for Certainty*. He claims to be 'Deweyan' and comments explicitly on Dewey's writings. While this claim has been disputed by Westbrook (1991) and Eldridge (1998), Rorty's influence on contemporary thought has contributed to a renewed interest in Dewey's work.

There is renewed interest in Dewey's theory of democracy. Westbrook, in his seminal study (1991), has made explicit the relevancy and actuality of the Lippmann–Dewey debate for American democracy at the end of the twentieth century, and the time of that study's publication and its wide reception coincided with a similar appeal for the systematic pursuit of community by a group of philosophers (e.g., M. Dancer) and sociologists (e.g., R. N. Bellah) referred to as 'communitarians.' Perhaps it is indicative of a renewed influence of Dewey's concept of 'great community' that J. Habermas closed a review of the publication in German, after 70 years, of *Quest for Certainty*, expressing the wish: "He (Dewey) would be the better patron for the Berlin Republic."

Abstract

Diabetes mellitus refers to a group of chronic diseases characterized by a disorder of carbohydrate metabolism. The most common forms are type 1 diabetes mellitus, type 2 diabetes mellitus, and gestational diabetes. Diabetes requires lifelong intense self-management behavior on a daily basis, and prognosis is heavily dependent on the individual's ability to successfully perform diabetes self-management. Thus, behavioral and psychosocial aspects play an important role in diabetes. Understanding how psychosocial risk factors and protective factors affect self-management and subsequently prognosis in individuals with diabetes constitutes a major concern in improving diabetes care and maintain the patients' quality of life.

Diabetes Mellitus

Diabetes mellitus is a group of metabolic diseases characterized by chronic hyperglycemia (high blood glucose levels) due to an abnormality in insulin production, its utilization, or both (Davidson et al., 2004). Currently, more than 371 million people worldwide are suffering from diabetes (International Diabetes Federation, 2012). With about 90–95% of all cases, the most common form is type 2 diabetes mellitus (T2DM), which results from a progressive insulin deficiency caused by insulin resistance. In addition to genetic factors, lifestyle factors such as obesity, unhealthy diet, and physical inactivity play an important role in the etiology of insulin resistance in T2DM. Type 1 diabetes (T1DM) comprises about 5–10% of all cases and results from a destruction of β-cells in the pancreas leading to an absolute insulin deficiency. The destruction of β-cells is often caused by progressive autoimmune processes. Gestational diabetes occurs in about 1–14% of all pregnancies and – in most cases – ends with giving birth. However, women with gestational diabetes are at higher life-time-risk of developing T2DM.

There are also other rare specific types of diabetes caused by genetic defects or drug- or chemical-induced forms.

T2DM is mostly diagnosed at 45 years of age or later. With respect to age range, prevalence rates increase continuously from 50 years, with the highest prevalence of T2DM in individuals aged 70–79 years (about 20%). An increase for T2DM in obese children and adolescents has been observed in the last years. T1DM can occur at any age but incidence rates are elevated in children and adolescents aged 10–14 years. Incidence rates decrease after puberty and stabilize between ages 15 and 29 years. About one quarter of all T1DM cases are diagnosed during adulthood (see Maahs et al., 2010, for an overview).

Prognosis

Diabetes may lead to short- and long-term diabetes complications: Short-term complications include diabetic ketoacidosis (diabetic coma) and hypoglycemia. Diabetic ketoacidosis refers to a state characterized by hyperglycemia and elevated levels of ketones in the bloodstream resulting from a breakdown of fatty acids. Ketoacidosis can lead to unconsciousness, diabetic coma, and is fatal if untreated. Hypoglycemia refers to low blood glucose levels, mostly caused by too high insulin dosage, inaccuracies in estimating one's carbohydrate uptake, or increased physical activity. Low blood glucose levels are associated with symptoms such as trembling, sweating, blurred vision, or difficulties to concentrate. If blood glucose levels are very low and brain glucose metabolism is compromised, unconsciousness, coma, and seizure may occur (severe hypoglycemia).

Long-term complications are caused by chronic hyperglycemia, leading to damage at small and large blood vessels (microangiopathy and macroangiopathy) as well as damage to nerves (neuropathy). Frequent clinical syndromes resulting from microangiopathy are diabetic nephropathy and diabetic retinopathy, which can lead to renal failure and loss of vision. Macroangiopathic complications include atherosclerotic processes associated with increased risk for coronary artery disease, periphery artery disease, and cerebrovascular diseases. Diabetic neuropathy can affect peripheral nerves, leading to symptoms such as pain, paresthesia, or loss of sensation in the affected regions and constitutes a risk factor for diabetic foot-ulcers, which is the major cause for amputations in diabetes. Diabetic neuropathy of the autonomic nervous system can impair the function of various organs such as the cardiovascular system, gastrointestinal tract, or genitourinary tract. For instance, a common clinical outcome of autonomic neuropathy in diabetes is erectile dysfunction. Diabetes is associated with increased mortality and reduced lifeexpectancy: In 2011 about 8% of all deaths in people aged 20–79 years were attributable to diabetes, and half of the people dying from diabetes were younger than 60 years of age (International Diabetes Federation, 2012). Good glycemic control, i.e., glucose levels as close to normal (nondiabetic) levels as safely possible, and avoiding hypoglycemia and hyperglycemia, is necessary to minimize the risk for acute as well as long-term complications and to improve prognosis. As glucose binds to hemoglobin in the red blood cells, glycosylated hemoglobin (HbA1C) can be used as a marker of glycemic control. Due to the average lifetime of a red cell of about 120 days, HbA1C reflects average blood glucose levels of the last 2–3 months.

Self-Management in Diabetes

Good glycemic control and, hence, prognosis in diabetes are highly dependent on the individual's skills to successfully perform diabetes self-management behavior in everyday life. Diabetes self-management is complex and differs between types of diabetes. In patients with T1DM, insulin treatment is mandatory from the onset due to the destruction of the insulin producing β-cells. Patients have to measure their blood glucose levels multiple times per day, estimate carbohydrate content of meals, calculate insulin dosages, and inject insulin. This requires knowledge about blood glucose metabolism and its external and internal influences, self-management skills as well as motivation and self-efficacy beliefs with respect to the treatment.

In patients with T2DM, the first-line treatment approach consists of lifestyle modification including healthy diet, physical activity, and weight reduction to improve insulin sensitivity. Oral antidiabetics are recommended in addition to lifestyle-modification or if lifestyle modification alone has not been sufficient. During the course of diabetes, insulin treatment is also necessary in most patients with T2DM. If target blood glucose levels are not reached, insulin treatment should be considered as soon as possible to avoid long-term complications. Lifestyle modification and adherence to oral antidiabetics also require sufficient knowledge, self-efficacy, and motivation from the person affected.

Thus, diabetes self-management is a daily burden that requires life long adherence and is influenced by behavioral and psychosocial aspects.

Psychosocial Aspects in Diabetes

With respect to psychosocial aspects, diabetes-specific problems such as self-management related problems, impaired hypoglycemia awareness (IHA), diabetes-specific fears, and mental disorders such as depression, anxiety, and eating disorders can be distinguished.

In the following passages diabetes-specific problems will be outlined first; in the second part prevalence, etiology, and impact of mental disorders in diabetes patients will be summarized.

Questionnaires that might be helpful in screening for diabetes-specific problems are displayed in **Table 1**. Mental disorders should be assessed using established diagnostic instruments based on criteria of the *International Classification of Diseases* (*ICD-10*) or the *Diagnostic and Statistical Manual of Mental Disorders* (DSM V), respectively.

Diabetes-Specific Psychosocial Aspects

Self-Management

Similar to other chronic diseases, quality of life may be reduced in patients with diabetes. Coping with the fears of acute and long-term complications and integrating self-management in daily life are important issues in diabetes. Results from the cross-national Diabetes Attitudes, Wishes and Needs (DAWN) study (Peyrot et al., 2005) showed that psychological well-being was poor in almost half of the study participants and diabetes-related worries such as the fear of deterioration of diabetes or worries about hypoglycemia were common, albeit a broad range between 25 and 50% across the different countries was observed. Only about 39–46% of all patients reported complete success in adherence in at least two thirds of their self-care domains. Self-reported adherence to diet and exercise was significantly lower than adherence to medication or appointment keeping. Most providers reported that they were aware of these psychosocial problems, but they indicated difficulties with respect to treatment such as a lack of confidence in their skills to manage psychosocial problems. These results highlight the need to identify patients with diabetes-related distress and to develop interventional tools for providers. Thereby, providers might able to help their patients in overcoming these problems.

Directly related to treatment and adherence in T2DM is psychological insulin resistance (PIR). PIR is a cross-national phenomenon, and refers to the reluctance to start insulin treatment due to various attitudes, beliefs and expectation with regard to insulin and diabetes. Studies examining PIR in insulin-naive T2DM patients indicate that feelings of personal failure, low self-efficacy, expected hardship from insulin therapy, negative outcome expectancy with respect to insulin, worries about increased risk of hypoglycemia, or fear of injections among others may contribute to PIR. PIR can lead to a delay in necessary insulin treatment with the subsequent risk of poor glycemic control. With respect to the DAWN-study population, more than 50% of insulin-naive T2DM patients reported worries about starting insulin treatment. Interestingly, this reluctance is observed in both patients and providers, with providers reporting similar concerns as their patients. Expected problems with adherence to insulin treatment and extra-time required for training insulin-self-management skills may also be among the reasons for a delay of insulin therapy (see Peyrot et al., 2010, for an overview). But as most of the studies were cross-sectional, it remains unclear, whether patients' and providers' psychological insulin resistance does actually delay insulin initiation and worsen glycemic control via non-adherence to treatment. However, these results indicate the need to address potential barriers when discussing insulin treatment with the patient.

Hypoglycemia Awareness

Hypoglycemia awareness refers to the ability to perceive the onset of hypoglycemia. In case of IHA, it becomes difficult to

detect the warning signs of hypoglycemia, and timely treatment of low blood glucose is often compromised. As a consequence, the risk for severe hypoglycemia and hypoglycemia-induced complications increases. IHA is associated with an up to six times higher risk for severe hypoglycemia compared to those with good/normal hypoglycemia awareness. IHA also constitutes a psychosocial burden for affected patients as well as for their relatives, because the fear to experience a hypoglycemia and not being able to detect hypoglycemia warning symptoms in time may lead to a feeling of helplessness and loss of control. IHA affects about 19–25% of T1DM patients and is less frequent in insulin-treated T2DM patients with incidence rates about 8–10%. Additional risk factors for IHA in insulin-treated patients are age, diabetes duration, strict glycemic control, and low diabetes knowledge (see Graveling and Fisher, 2007, for an overview).

The development of IHA has physiological and behavioral components: If hypoglycemic episodes are experienced frequently, a physiological adaptation to lower blood glucose levels occurs. As a consequence, the hormonal counterregulation that causes the typical first symptoms of hypoglycemia is altered, i.e., the threshold for the counterregulation processes shifts toward lower blood glucose. Thus, warning symptoms occur at lower blood glucose levels, and the possibility of a timely treatment of decreasing blood glucose is reduced. As a consequence, moderate and severe hypoglycemic episodes are more likely, leading to further shift of the hypoglycemia symptoms threshold. A vicious circle can develop. On the behavioral side, the individual decision to treat decreasing blood glucose plays an important role. If the patient decides not to treat hypoglycemic levels timely, hypoglycemic episodes are more likely and symptom threshold shifts further. Possible reasons not to treat hypoglycemia include underestimation of the individual risk of severe hypoglycemia, poor interoception, fear of diabetes complications, or situational factors complicating a timely treatment. Treatment approaches to IHA comprise the rigorous avoidance of hypoglycemic episodes to reverse the adaptational processes that led to lower thresholds for hypoglycemic symptoms, educational programs consisting of symptom perception training such as the blood glucose awareness training (BGAT, Cox et al., 2006), or more empowerment-based approaches with a focus on personal goal-setting, self-management, and coping skills to prevent and treat hypoglycemia (HyPOS, Hermanns et al., 2010).

Studies examining hypoglycemia mostly conclude that the experience of frequent episodes of severe hypoglycemia often occurs in a high risk subgroup of patients, which may also be at increased risk for IHA. Identifying these patients and the physiological, behavioral, and psychosocial influences that contribute to heightened risk in these patients should be of special importance.

Diabetes-Specific Fears

The most common forms of diabetes-specific fears are fear of hypoglycemia and fear of diabetes complications.

Fear of hypoglycemia refers to a distinct fear to experience hypoglycemia that is associated with avoiding behaviors in order to minimize the possibility of hypoglycemia. Patients often develop fear of hypoglycemia after experiencing a severe hypoglycemic episode, which can be a very aversive experience with strong feelings of helplessness and lack of control. Additionally, individuals might feel embarrassed when they experienced hypoglycemia in public, and outside help from stranger was required. Typical avoidance behaviors include aiming at higher blood glucose levels than recommended, excessively monitoring blood glucose to avoid an undetected decrease in blood glucose, omitting or reducing insulin doses, eating more carbohydrates, and avoiding physical activity because it could decrease blood glucose level. Some patients even try not to leave their home due to the fear to experience hypoglycemia in public. Thus, fear of hypoglycemia can be a major burden for people affected. Consequences with respect to glycemic control can also be severe: The above-mentioned avoidance behaviors can lead to higher average blood glucose levels, and risk of ketoacidosis and late complications are increased. The prevalence of fear of hypoglycemia is difficult to determine. Due to the fact that more T1DM patients than T2DM patients are treated with insulin, hypoglycemic episodes and in consequence fear of hypoglycemia are more common in T1DM.

Fear of diabetes complications refers to the constant and excessive fear to develop late complications such as loss of vision or diabetic foot syndrome in the course of diabetes. Patients suffering from this fear often have unrealistic or pessimistic beliefs about the association of elevated blood glucose levels and risk of diabetes complications or overestimate their individual risk of diabetes complications. Subsequently, avoiding behaviors can develop such as excessively monitoring of blood glucose, aiming rigidly at meeting strict target levels for blood glucose, or setting themselves lower target levels than recommended. Psychosocial burden in patients affected by fear of diabetes complications is high and consequences for glycemic control can also be severe. Trying to meet target levels in a rigid way can increase the risk for hypoglycemic episodes even in patients without fear of diabetes complication. However, as patients suffering from this fear may be less likely to treat mild hypoglycemic episodes, risk for severe hypoglycemia, and hypoglycemia-induced complications such as unconsciousness or seizure is increased. Furthermore, frequent episodes of hypoglycemia can also lead to an elevated risk of developing an IHA.

Treatment approaches depend on the severity of the experienced fears: With respect to severe forms of fear and distinct avoiding behaviors, established psychotherapeutic approaches for anxiety disorders, best conducted by a psychologist with knowledge about diabetes or in close collaboration with the diabetologist, are indicated. In case of milder forms, discussing the fears with the diabetologist might be sufficient.

Mental Disorders in Diabetes

Depression

There is a large body of evidence that prevalence of depression in diabetes patients is about twice as high as in individuals without diabetes. Prevalence rates vary depending on criteria (diagnosis of depression vs depressive symptoms) and assessment of depression (questionnaires vs structured diagnostic interviews). Depressive disorders as well as subclinical levels of depression are associated with poorer adherence to treatment, worse glycemic control, elevated risk for diabetes complications, cardiovascular disease, and increased all-cause mortality

as well as increased cardiovascular mortality compared with diabetes patients without depressive symptoms. Depression risk is increased in females with diabetes, directly after experiencing severe hypoglycemia, and at first occurrence of long-term complications. An increasing number of diabetes complications is also associated with increased depression risk. However, as most studies examined individuals with T2DM, the results are clearer for T2DM patients than T1DM patients.

With respect to T2DM, recent studies indicate that the relationship between diabetes and depression may be bidirectional – with an increased risk for depression in patients diagnosed with T2DM and vice versa an increased risk for T2DM in individuals with depression. The pathways relating both diseases are still unclear and range from behavioral factors such as poor health behaviors and reduced adherence to pathophysiological explanations such as increased inflammation or alterations in hypothalamic–pituitary–adrenal axis function. A recent meta-analysis on the role of hyperglycemia for depression risk in diabetes concluded that prevalence of depression was only elevated in individuals diagnosed with T2DM, but not in patients with undiagnosed diabetes or impaired glucose tolerance (Nouwen et al., 2011). These results indicate that the psychosocial burden of knowing to have a chronic disease like diabetes is not to be neglected with respect to the development of depression.

Established approaches in treating depressive disorders should be used in patients with diabetes. However, with respect to antidepressive medication, selective serotonin reuptake inhibitors should be recommended because of fewer metabolic side effects. Interestingly, current research indicates that psychotherapy and antidepressant medication both improve depression outcomes in diabetes, whereas diabetes outcomes such as glycemic controls could not be improved in most studies.

To conclude, although it is almost common knowledge that depression is frequent in diabetes and adversely affects prognosis, specific pathways linking both diseases remain still unclear. In addition to studies with regard to the currently discussed psychophysiological pathways, further research examining alterations in cerebral activation and neuronal connectivity using imaging techniques might contribute to a better understanding of this relationship.

Anxiety

With respect to prevalence of anxiety disorders in diabetes there is less research than for depression and diabetes. Results from the World Mental Health Surveys (Lin et al., 2008) are the first to indicate that anxiety disorders are about 20% more frequent in patients with diabetes relative to those without diabetes. Differences in prevalence of specific anxiety disorders could not be proven. Anxiety disorders can also have diabetes-specific content such as fear of hypoglycemia or fear of diabetes-complications. Although these diabetes-specific fears are mostly subclinical, in some cases criteria of anxiety disorders may be met. For example, fear of hypoglycemia can present as a specific phobia, or fear of diabetes complications can be part of a generalized anxiety disorder. In these cases, patients may benefit most from a combination of psychotherapeutic interventions established in the treatment of anxiety disorders by a psychotherapist with background medical knowledge about diabetes mellitus and its self-management. With respect to the consequences of anxiety disorders in diabetes not much is known – but it has to be assumed that anxiety disorders might adversely affect prognosis in diabetes.

Further studies are necessary to explore the relationship of anxiety and diabetes.

Eating Disorders and Disordered Eating Behaviors

With respect to prevalence of eating disorders and disordered eating behavior (DEB) in diabetes, research results are heterogeneous. Whereas some studies indicate elevated rates of eating disorders and DEB in diabetes patients, other studies do not find any differences (see Young-Hyman and Davis, 2010, for an overview). In addition, methodological issues hamper the interpretation of these results: Many studies did not include weight-matched controls or focused on women. The use of existing measures to assess DEB may not be adequate for patients with diabetes: Self-management skills such as carbohydrate counting and attitudes toward food and food intake that may reflect functional behaviors and cognitions in diabetes may be wrongly diagnosed as dysfunctional by these instruments.

However, various studies indicate that DEB such as binge eating, restrained eating, self-induced vomiting are common in diabetes. Insulin purging, a diabetes-specific form of DEB, is of particular importance and occurs more frequently in T1DM. Insulin purging refers to the omission of insulin to avoid weight gain or to compensate for eating binges. Omission of necessary insulin leads to high blood glucose levels, and in consequence, body fat is metabolized. In addition to weight loss, this increases the risk of diabetic ketoacidosis, and long-term complications. Cross-sectional studies indicate that HbA1C levels tend to be higher in diabetes patients with subclinical or clinical eating disorders, and diabetes complications such as retinopathy or neuropathy as well as hospitalizations and diabetic ketoacidosis are more common in these patients. Due to the negative consequences of DEB, it is important to consider the possibility of DEB in patients with diabetes. Possible indicators of DEB include underweight, large fluctuations in HbA1C and/or body weight, or decompensation of glycemic control. With respect to treatment of eating disorders, established treatment approaches similar to those without diabetes are recommended. For cases with insulin purging, a close collaboration between psychotherapists and diabetes care specialists is indicated. Further studies should aim at addressing the methodological issues mentioned above and at developing measures that can discriminate between diabetes-specific functional occupation with eating and dysfunctional forms of eating behavior that result from unrealistic beliefs about body image or thinness.

Conclusion and Further Research

As a chronic disease requiring lifelong self-management, behavioral and psychosocial aspects play an important role in diabetes. Diabetes-specific problems such as the psychosocial burden of self-management, fears of acute or long-term diabetes complications, or IHA can compromise diabetes

management and glycemic control. In addition, mental disorders such as depression or anxiety are more prevalent in diabetes compared with healthy controls. Even subclinical forms of mental disorders such as disordered eating behaviors may adversely affect glycemic control. To ensure successful diabetes-management addressing psychosocial issues is a key element in the treatment of diabetes. More research is necessary to identify patients at risk for psychosocial problems and to develop treatment approaches that can improve psychosocial as well as medical outcomes.

Due to the increase of T2DM in children and the high prevalence of diabetes in the elderly, new challenges for psychosocial research in diabetes emerge: As the role of behavioral and psychosocial factors for prognosis in these age groups is not well understood yet, future research addressing these aspects could help improving diabetes care and maintain these patients' quality of life.

Diagnostic Processes in Clinical Psychology and Psychotherapy

Abstract

A person is assigned a diagnosis of a mental health disorder if he or she meets the minimum number of criteria for that diagnosis according to an established classification system like the Diagnostic and Statistical Manual or the International Classification of Diseases. Diagnoses are determined through the process of psychological assessment, which, at minimum, includes a clinical interview, but can also include data from self-report inventories, behavioral observation, assessment of intellectual functioning, thought sampling, and projective testing. Although many established assessment tools have adequate reliability and validity, the diagnostic process also relies upon the clinical judgment of the clinician, which at times can be subject to bias. Current issues and trends in diagnostic processes include the development and evaluation of (1) clinical interviews that correspond to recently revised diagnostic criteria, (2) user-friendly screening tools, (3) computerized assessments, and (4) alternatives to categorical diagnostic systems.

Definitions

According to the Diagnostic and Statistical Manual of Mental Disorders – fifth Edition (DSM-5; APA, 2013), "a *mental health disorder* [italics added] is a syndrome characterized by clinically significant disturbance in an individual's cognition, emotion regulation, or behavior that reflects a dysfunction in the psychological, biological, or developmental processes underlying mental functioning" (p. 20). In order to be assigned a *diagnosis* of a mental health disorder, a person must meet an established number of criteria that are indicative of a particular diagnosis. Mental health professionals, such as clinical psychologists and psychiatrists, are trained to conduct assessments of the presence and severity of psychiatric symptoms, as well as the degree to which psychiatric symptoms are associated with life interference and subjective distress, in order to determine the diagnosis of mental health patients.

There are currently two comprehensive systems that guide the diagnosis of mental health disorders. The *International Classification of Diseases* (ICD) is a health care classification system spearheaded by the WHO that categorizes both medical and mental health illnesses. It is currently in its 10th edition, with an 11th edition in development that is to be submitted to the WHO's World Health Assembly for official endorsement in by 2015. The DSM is a classification system specifically for mental health disorders that was developed by the American Psychiatric Association in 1952, the fifth edition of which was released in 2013. In the United States, health care professionals use ICD codes to designate diagnoses of all diseases and illnesses other than those that are considered mental health disorders, and they use the DSM to designate diagnoses of mental health disorders. Although the ICD is an international classification system, many clinicians outside the United States use the DSM. The WHO formed a DSM–ICD Harmonization Coordinating Group in 2009 with the aim of making the DSM-5 and ICD-11 diagnoses as uniform as is possible, which is a formidable task because only 1 of the 176 sets of diagnostic criteria present in previous versions of both classification systems was identical (First, 2009).

Psychological assessment is the process by which a clinician administers one or more assessment tools in order to gain comprehensive knowledge about a patient's current and past cognitive, emotional, and behavioral experiences, as well as about the patient's current and past life circumstances. An assessment tool can be a clinical interview, a psychological test, on observation, or even a physiological measurement. Among the many purposes of psychological assessment are the identification of acute and chronic life stressors that are exacerbating emotional distress, an understanding of the patient's level of functioning, the construction of a patient's personality profile, the assessment of the patient's strengths, and the development of a treatment plan that targets the most salient aspects of the patient's clinical presentation. However, perhaps the most fundamental purpose of psychological assessment is to arrive upon one or more mental health disorder diagnoses.

Current Knowledge and Schools of Thought

An array of assessment tools is available to assist mental health providers in determining accurate mental health disorder diagnoses. Some of these assessment tools measure the frequency and severity of psychiatric symptoms and cut across different theoretical orientations, whereas other assessment tools were developed within one particular theoretical orientation and yield data that advance a conceptualization on the basis of that theoretical orientation.

Clinical Interviews

According to Groth-Marnat (2009), "Probably the single most important means of data collection during psychological evaluation is the assessment interview" (p. 65). Clinical interviews can range from being unstructured and general to

 http://dx.doi.org/10.1016/B978-0-08-097086-8.21030-1

those that are structured or semistructured and that specifically target DSM or ICD symptoms of mental health diagnoses. The advantages of using a structured or semistructured clinical interview are that they (1) include carefully crafted questions that cover each criterion that contributes to the diagnosis of a mental health disorder, (2) have research demonstrating their strong psychometric properties (see Section Methodological Issues), and (3) are considered the 'gold standard' method of establishing mental health disorder diagnoses.

Structured and semistructured clinical interviews typically included several layers of questions. *Screening questions* are those that are first administered to respondents to assess the likelihood of meeting diagnostic criteria for a mental health disorder. Those who respond negatively to one or more screening questions for a mental health disorder are assumed not to meet diagnostic criteria for the disorder, and no further questions are asked. Those who respond affirmatively to one or more screening questions are asked an additional set of questions that correspond to the diagnostic criteria for that particular mental health disorder. Clinicians who administer the clinical interview are trained to assess for the presence or absence of each criterion, often assigning an indicator of whether the criterion is absent, present at a subthreshold level of clinical significance, or present at or above the threshold of clinical significance. Mental health disorder diagnoses are assigned to respondents when they meet the minimal number of diagnostic criterion at or above the threshold of clinical significance. Diagnoses can be assigned according to two time frames: (1) lifetime and (2) current (typically defined as occurring within the previous 12 months).

Structured and semistructured clinical interviews were developed mainly for research purposes, but they have been increasingly incorporated into clinical practice (Groth-Marnat, 2009). They are used most typically by clinicians who valued evidence-based practice and who have received training in the administration of these instruments, often in the context of research conducted in psychology and psychiatry departments that house large grant-funded clinical research. In the United States, perhaps the most commonly used structured or semistructured clinical interview is the Structured Clinical Interview for DSM Disorders (SCID), most recently developed to assess DSM-IV-TR (APA, 2000) diagnoses (First et al., 1996), and currently being adapted to assess DSM-5 diagnoses (see www.scid4.org). In addition, the WHO Composite International Diagnostic Interview (CIDI; Kessler and Üstün, 2004) yields diagnoses according to the 4th edition of the DSM and the 10th edition of the ICD. Administration of either of these instruments yields data to diagnose the major mental health disorders, including mood disorders, anxiety disorders, alcohol and substance use disorders, eating disorders, and other impulse control disorders.

In contrast, other clinicians, often who practise from a client-centered or psychodynamic orientation, use unstructured formats that allow patients to talk freely about their lives and 'tell their story.' Advantages of an unstructured approach include the opportunity to develop a strong sense of rapport, flexibility, and the potential to gather information about unique aspects of clients' lives (Groth-Marnat, 2009). The main disadvantage is that the reliability and validity (see Section Methodological Issues) of diagnoses that are made from this approach are unclear.

Self-Report Inventories

Self-report inventories, or *questionnaires*, are tools in which respondents answer a series of questions or make ratings of statements associated with cognitive, behavioral, and emotional characteristics of mental health disorders. Self-report inventories can ask respondents to indicate the presence or absence of these characteristics; the severity of the characteristics, often on a Likert-type scale; or the frequency of the characteristics. Many clinicians administer self-report inventories in addition to conducting a clinical interview because (1) they are usually easy to administer and complete, and (2) data obtained from them can be compared with normative data to yield information about where the patient stands relative to a people representative of the general population.

There are literally thousands of self-report inventories. Many of them are referenced in the Buros Mental Measurements Yearbook, a compilation of test reviews and evaluations that is now in its 18th edition (Spies et al., 2010), with a 19th schedule to be published in early 2014, or in the two volume compilation, *Measures in Clinical Practice and Research* by Corcoran and Fischer (2013a,b).

Many clinicians administer self-report inventories that assess a range of psychiatric symptoms in order to obtain a general sense of areas of concern for patients, with the idea that they will follow up on these areas using clinical interviewing in order to establish a diagnosis of a mental health disorder. For example, the Symptom Checklist-90-R (Derogatis, 1994) is a 90-item list of symptoms that requires respondents to rate their severity on a 5-point Likert scale (0 = not at all; 4 = extremely). The measure yields nine scores representative of specific clinical presentations (e.g., obsessive compulsive, phobic anxiety), as well as three global indices (e.g., Global Severity Index). Another commonly used measure to assess symptoms associated with an array of mental health disorders is the Patient Health Questionnaire (PHQ) (Spitzer et al., 1999), a self-report inventory that was developed from the Primary Care Evaluation of Mental Disorders (Spitzer et al., 1994). It assesses 11 major domains of symptoms, with a number of items corresponding to specific symptoms in these domains. It yields information to assist in the diagnosis of depressive, anxiety (particularly panic), somatoform, alcohol use, and eating disorders.

Other self-report inventories assess symptoms associated with one specific psychiatric disorder or clinical condition. One of the most common self-report inventories used in clinical research and practice to assist in arriving upon a diagnosis of major depressive disorder is the Beck Depression Inventory-II (BDI-II; Beck et al., 1996). The BDI-II is a 21-item inventory that requires respondents to endorse the severity of depressive symptoms on a 0–3 scale. It classifies respondents as having no or minimal, mild, moderate, or severe depressive symptoms, and research has shown that it can identify cases of depression as effectively as more costly and time-consuming structured interviews (Stukenberg et al., 1990). The lead developer of the BDI-II,

Dr Aaron Beck, has also developed similar inventories to assist in the diagnosis and conceptualization of other psychiatric disorders, including anxiety (Beck Anxiety Inventory; Beck and Steer, 1990), hopelessness (Beck Hopelessness Scale; Beck and Steer, 1988), and cognitive insight in schizophrenia (Beck et al., 2004). The PHQ, described previously, has also been adapted to assess symptoms of particular disorders, such as depression (i.e., PHQ-9; Kroenke et al., 2001) and generalized anxiety disorder (Spitzer et al., 2006).

In addition to these inventories that assess symptoms of major mental health disorders, there are also self-report inventories whose data yield important insights into the diagnosis of personality styles and disorders. The Minnesota Multiphasic Personality Inventory-2 (MMPI-2; Butcher et al., 2001) is a 567-item self-report inventory that yields scores for 10 clinical scales (e.g., hypochondriasis, depression), 10 validity scales (e.g., lie, infrequency), and 15 content scales (e.g., anxiety, fears). Rather than using responses on individual scales to facilitate the diagnosis process, clinicians evaluate the clients' elevations on some scales relative to other scales in order to identify particular personality profiles. The Millon Clinical Multiaxial Inventory-III (MCMI-III; Millon, 1997) is a 175-item self-report inventory that yields scores for 11 clinical personality patterns (e.g., avoidant, dependent), 3 severe personality pathologies (e.g., borderline), 7 clinical syndromes (e.g., anxiety, somatoform), and 3 severe syndromes (e.g., thought disorder), as well as 4 validity scales (e.g., disclosure). Scores from the MCMI yield important data that can assist clinicians in making personality disorder diagnoses (i.e., Axis II diagnoses according to the DSM).

Other Assessment Tools

Assessment tools need not be limited to those in which clients respond to straightforward questions about their behavior and psychological experiences, either via clinical interview or self-report. For example, *behavioral observation* is a tool in which a clinician establishes, a priori, behavioral manifestations of a mental health disorder, as well as their antecedents and consequences, and then observes the frequency of the behaviors in a particular individual within a particular time frame. It is used most frequently by clinicians with a behavioral orientation in order to establish specific targets for behavior therapy. *Assessment of intellectual functioning* (e.g., Wechsler Adult Intelligence Scale-IV (WAIS-IV; Wechsler, 2008a) and Wechsler Intelligence Scale for Children (Wechsler, 2008b)) is done to establish an index of a person's overall cognitive ability, as well as specific cognitive functions such as verbal ability and short-term memory. It is administered most frequently to aid in the diagnosis of intellectual disability and learning disorders, as well as in the diagnosis of dementia-related disorders. *Thought sampling* is a tool in which respondents list their cognitive contents, or what is running through their minds, at predetermined intervals or in response to a particular stimulus. It is used most frequently by clinicians with a cognitive orientation in order to develop a case conceptualization and establish specific targets for cognitive therapy. *Projective tests* are tools that allow respondents to interpret ambiguous stimuli, with the idea that their responses provide insight into unconscious impulses or drives (e.g., The Rorschach (Rorschach, 1941) and Thematic Apperception Test (TAT; Morgan and Murray, 1935)). They are used most frequently by clinicians with a psychodynamic orientation.

Clinical Judgment

Clinical judgment is defined as a clinician's attempt to assimilate objective and subjective data gathered from a psychological assessment and arrive upon one or more diagnoses of a mental health disorder (cf Groth-Marnat, 2009). Clinical judgment affects psychological assessment on many levels. For example, clinicians use clinical judgment when they decide how to conduct their psychological assessment and the particular domains to be assessed. When administering clinical interviews, they use their judgment as to the kind of degree of clarification they ask of the patient in order to accurately determine whether they meet the diagnostic criterion under consideration at a level of clinical significance.

Although results from structured clinical interviews like the SCID and CIDI are usually considered the 'gold standard' in identifying diagnoses of mental health disorders, if additional assessment tools are included in a psychological assessment, then the clinicians use clinical judgment in determining the amount of weight they put on the data they obtained from various assessment tools and the manner in which they reconcile inconsistent data. Research has shown that clinicians often make errors in judgment when assimilating the results of psychological assessment in order to formulate a diagnosis of a mental health disorder. For example, some clinicians do not account for the base rate of the diagnosis in the general population (Hawkins and Hastie, 1990); others do not receive feedback regarding the accuracy and predictive ability of their diagnoses (Garb, 2005). In addition, research shows that information gathered earlier in an assessment is often given more importance than information gathered later in the assessment, resulting in a confirmatory bias in which clinicians do not thoroughly seek out data that will disconfirm their original impressions (Haverkamp, 1993). Groth-Marnat (2009) made eight recommendations for reducing bias in clinical judgments, including: (1) using comprehensive structured or semistructured clinical interviews to avoid missing important information; (2) considering evidence that is inconsistent with initial hypothesis; (3) paying careful attention to ICD or DSM criteria; (4) relying on careful note taking rather than on memory; (5) considering base rates of diagnoses being considered; (6) seeking feedback regarding the accuracy of clinical judgments; (7) staying abreast of the theoretical and empirical literature on the diagnosis under consideration; and (8) staying abreast of the literature on clinical judgment to be aware of new trends.

Treatment Planning and Psychotherapy

When a patient presents for treatment, he or she will typically undergo some sort of psychological assessment using the approaches described previously so that his or her mental health provider can arrive upon one or more diagnoses. The mental health provider and the patient then collaboratively

develop a treatment plan in which specific targets for treatment are identified. The treatment plan is shaped, at least in part, by the mental health disorder diagnosis(es) that the patient has been assigned. There are many manualized treatments that have been developed for specific mental health disorder diagnoses, and many mental health providers will administer the treatments described in these manuals to alleviate their patients' mental health disorder. A caveat to this statement, however, is that the majority of published treatment manuals describe cognitive, behavioral, or cognitive behavioral treatments, and clinicians who practice from other theoretical orientations may choose other approaches to treatment even if a treatment manual is available for the specific diagnosis that they have assigned to their patient.

It is also important to acknowledge that many psychological processes cut across diagnostic categories. Critics of manualized treatments observe that the number of treatment manuals that mental health providers must learn is unwieldy (Beutler, 2000). Thus, there is movement toward developing psychotherapeutic approaches that are transdiagnostic in nature and that are based on evidence-based psychological principles (e.g., Barlow et al., 2004) rather than on entire treatment packages that are limited to one specific mental health disorder diagnosis. In their manual on the transdiagnostic treatment of emotional disorders (e.g., depression, anxiety), Barlow et al. (2011) indicate that the core features of emotional disorders are inappropriate emotional responding, lack of skill in emotion regulation, and a perception that one does not have the ability to manage emotional responses, and they describe corresponding strategic interventions that target these cognitive, behavioral, and emotional processes regardless of the specific diagnosis that is assigned to the patient.

Methodological Issues

For psychological tests to be useful, they must have adequate psychometric properties. The two most important psychometric properties are reliability and validity. *Reliability* refers to the stability and consistency of data obtained by the psychological assessment. Reliability is demonstrated when the assessment tool yields the same results if the person takes the test on a different occasion or if the test was administered by a different clinician. The higher an assessment tool's reliability, the less chance there is that measurement error influenced the results. An assessment tool's reliability can be calculated in four ways. An estimate of *test–retest reliability* is determined by correlating the scores yielded by an assessment tool administered on two separate occasions. An estimate of *alternative forms reliability* is determined by correlating the scores yielded by two supposedly equivalent versions of an assessment tool administered on two separate occasions. In contrast, an estimate of *internal consistency* can be obtained in a single administration of the assessment tool. It is calculated by obtaining correlations between responses to specific items on the test, with the idea that the correlations should be high if the items are all measuring the same construct. Finally, an estimate of *interrater reliability* is determined by correlating the scores of an assessment tool, which is either administered on two separate occasions with two different test administrators, or it is administered on one occasion and scored by two different individuals. Because estimates of reliability are based on correlations, they always range from 0.0 to 1.0, with higher numbers indicative of higher reliabilities.

Validity refers to the extent to which the assessment tool is measuring what it is supposed to measure. There are several ways to establish the validity of an assessment tool. *Content validity* refers to the degree to which the items on an assessment tool are representative of and relevant to the construct being measured. *Criterion validity* is an estimate of the degree to which data obtained from an assessment tool correlate with performance on other measures assessing similar constructs. There are two types of criterion validity. *Concurrent validity* refers to the correlation between measurements taken at the same time, such as two assessment tools measuring similar constructs that are administered in a single sitting. *Predictive validity* refers to the correlation between an assessment tool administered on one occasion and data obtained at a later-time, such as a measure of psychotic symptoms upon admission to the hospital and the number of days the patient stayed in the hospital. *Construct validity* is the degree to which an assessment tool measures a theoretical construct or trait. It is often obtained by examining the degree to which data obtained from an assessment tool correlate with data obtained by measures of a similar theoretical construct (i.e., *convergent validity*), as well as the degree to which data obtained from an assessment tool do not correlate with data obtained by measures of a dissimilar theoretical construct (i.e., *discriminant validity*). *Face validity* refers to the degree to which the items on the assessment tool are sensible to the test taker, which can affect the manner in which the test taker approaches the assessment. Finally, *incremental validity* refers to the degree to which the results from any one assessment tool yield information above and beyond that obtained by other assessment tools, which has implications for the efficiency of the psychological assessment process and its cost-effectiveness.

These psychometric constructs have important implications for the process of achieving a mental health diagnosis. Clinicians should use assessment tools with adequate reliability and validity in order to ensure the accuracy of the mental health diagnosis. In addition, they should choose their assessment tools carefully so that the data obtained from each assessment tool yield unique information and so that the assessment battery is not unwieldy, as a lengthy assessment battery is associated with patient fatigue and boredom.

Another methodological issue to consider in using assessment tools is the degree to which they accurately identify patients with the particular mental health diagnosis under consideration. *Sensitivity* refers to the percentage of true cases of the mental health diagnosis that are identified by the particular assessment tool, whereas *specificity* refers to the percentage of true negatives that are identified by the particular assessment tool. Ideally, an assessment tool would be characterized by high levels of both sensitivity and specificity. However, in reality, sensitivity and specificity covary, such that specificity often decreases when sensitivity increases, and sensitivity decreases when specificity increases. The optimal ratio of sensitivity to specificity depends on the costs and benefits

of identifying a large number of false positives and of missing true negatives.

Change in Focus or Emphasis Over Time

Psychological assessment is central to the training, and even to the identities, of clinical psychologists. However, the amount of time that clinicians devote to psychological assessment has decreased substantially as the role of psychologists has expanded beyond test administration (Groth-Marnat, 2009). Surveys of psychological test usage have shown that the 10 most frequently used tests have remained remarkably stable over the past several decades and include many of the assessment tools mentioned previously, such as the BDI, MMPI, WAIS, Rorschach, and TAT (Camara et al., 2000). At the same time, there has been a decrease in the use of projective tests (Piotrowski, 1999), which could be due to multiple factors such as their questionable norms and validity, the extensive time required to learn their administration, and the availability of more cost-effective assessment tools (Groth-Marnat, 2009). Another change that has occurred over the second half of the twentieth century and into the twenty-first century is that the pool of available diagnoses has greatly expanded, requiring modern clinicians to be cognizant of and potentially assess for many mental health disorders that had not been considered by clinicians in the past.

Current and Emerging Directions in Theory and Research

Four emerging directions in theory and research associated with diagnostic processes deserve note. First, new versions of structured clinical interviews are being developed, which assess mental health disorders that correspond to the newest versions of the DSM and ICD. A host of empirical research will emerge from these developments, such as research that establishes the psychometric properties of these interviews, as well as epidemiological research that establishes the prevalence and incidence of mental health disorders according to these most recent diagnostic criteria. Second, there is a pressing need to identify effective, yet quick and user-friendly, screening tools that identify individuals that likely meet criteria for mental health disorders in settings such as primary care, obstetrics and gynecology, and pediatrics. Not only does research on this topic focus on the psychometric properties (e.g., sensitivity and specificity) of these screening tools, but it also examines the degree to which identified individuals follow through with referrals for treatment and barriers to implementing screening programs in nonmental health settings. Third, the era of managed care has prompted research into cost-effective mental health procedures. Relevant to diagnostic processes is the increasing reliance on computerized assessment. Research on this topic not only establishes the psychometric properties of these instruments, but also their correspondence with diagnoses arrived upon by face-to-face contact with a clinician. Finally, there has been long-standing debate about the best approach to diagnosing mental health disorders, and particularly personality disorders, in the DSM, with one side arguing for a categorical approach, and the other side arguing for a dimensional approach (Simonsen, 2010). In fact, a dimensional approach to diagnosing personality disorders (i.e., Axis II disorders) was considered for the DSM-5 (Skodol, 2010), but ultimately not adopted. However, research will continue to examine alternative approaches to categorical diagnosis and the degree to which their utility exceeds categorical approaches.

Abstract

Dialectology, the systematic study of language variation, had its effective beginnings in Europe after 1850, but it has its roots in an age-old fascination with accent and dialect. Dialectology first evolved as a classificatory discipline that concentrated mainly on the speech patterns of the most conservative speakers, called NORMs, an acronym for nonmobile, older, rural males. Its consummation came with the *Atlas linguistique de France* (10 Vols., 1901–13) directed by Jules Gilliéron at the Sorbonne, which provided an influential precedent for 75 years. The rise of linguistics after 1916 brought with it initiatives for integrating dialectology, but these were mostly resisted. As social changes in the second half of the twentieth century diminished the rural, uneducated, isolated populaces that had been the dialectologists' object of study, the discipline declined. However, it was revitalized by two concurrent forces, one technological and the other methodological. The first is computerization, which provides dialectologists with the means of managing the superfluity of data that had been both its strength and its burden. The second is sociolinguistics, the study of language variation on social-science principles, which defines its domain more inclusively in terms of populations and social settings. Dialectology, thus reformed, has again become a thriving intellectual enterprise.

Dialectology, the systematic study of linguistic variation, began as an autonomous discipline in the second half of the nineteenth century and became subsumed as a branch of linguistics in the second half of the twentieth century, though not without difficulty. Today it has worldwide currency and hundreds of active participants engaged in diverse research.

Beginnings

Its beginning is conventionally dated as 1876, when the German professor Georg Wenker mailed a list of sentences written in standard German to schoolmasters in the north of Germany and asked them to return the sentences to him transcribed into the regional dialect of their school districts. Wenker made further mailings until 1887 by which time he had blanketed the entire nation. He ultimately sent his list to nearly 50 000 schoolmasters, and he received completed forms from 45 000 of them, The schoolmasters, with few guidelines and no precedents, provided Wenker with thousands of regional variants of all kinds: lexical, pronunciation, phonological, morphological, and syntactic. Overburdened by data, Wenker was forced to limit his analyses to a few variants found in a closely circumscribed area of north and central Germany, which he then painstakingly transcribed by hand onto two sets of maps bound as *Sprachatlas des Deutschen Reichs* and deposited in Marburg and Berlin in 1881 (Wenker, 1881).

Thirty years before Wenker, the Finnish polymath Anto Warelius (1821–1904), approached the study of dialect from an entirely different perspective in a scholarly undertaking that remains virtually unknown outside his own country, but which has a prior claim over Wenker as the first truly systematic study. In 1846, Warelius set out on foot from Hamina in southeastern Finland and walked in a northwesterly line, eliciting and transcribing words and expressions from the villagers he encountered across almost 400 km (Rapolo, 1969; Chambers, 2000).

Warelius remains an obscure figure in the history of dialectology, but this method of eliciting dialect forms in face-to-face interviews with villagers foreshadowed the predominant method used by professional dialectologists for the next 150 years. The influential precedent for the method of direct fieldworker elicitation was set in 1896 by Jules Gilliéron, a Swiss professor at the Sorbonne in Paris, in the dialect survey of France. Gilliéron trained an obscure grocer, Edmond Edmont, in the craft of phonetic transcription, and dispatched him into the French countryside on his bicycle. Edmont has become a legendary figure in dialectology for his unflagging devotion as he pedaled into 639 villages and interviewed 700 *paysans* in less than 4 years. He sent his transcriptions to Gilliéron in Paris at intervals, where they were incorporated into a cumulative mapping enterprise, and publication of the maps began in 1901 and ended in 1910 with the thirteenth volume of the *Atlas linguistique de France* (ALF). Gilliéron and Edmont's atlas (1901–10) stands as an early consummation of dialect geography and became the influential precedent for future projects for almost a century.

Impetus

The motivation for these methodical, large-scale studies in the second half of the nineteenth century is conventionally held to be a reaction to Neogrammarian philology, one of the great intellectual currents of the day. The Neogrammarians demonstrated law-like regularities in the historical descent of modern languages from classical ones. One of their tenets was *Ausnahmslosigkeit der Lautgesetze* 'sound changes are exceptionless.' Such a hypothesis, bold and admirably empirical, invites refutation, and a likely source would come from dialect data gathered from highly differentiated, relatively isolated villages.

The view that the first dialectologists rose to the Neogrammarian challenge has romantic resonance, but it is not strongly supported by facts. Neither Wenker nor Gilliéron nor

any of their successors actually marshaled their data for elucidation, revision or refutation of any overriding linguistic principles, Neogrammarian or otherwise. In practice, the main results of their scholarship were descriptive rather than analytical, and their expressed goals aspired to no more. The *Sprachatlas* became the preferred medium for dissemination of results, with linguistic tokens carefully arrayed on geographic representations, usually with commentary on secondary variants which had to be omitted because they would overcrowd the map, and occasionally with isoglosses, lines drawn between locations where different variants tended to occur.

Rather than Neogrammarianism, the main impetus for dialectology as a systematic discipline appears to have been Linnaean taxonomy, another forceful current of nineteenth century intellectual history. Dialect data lends itself quite naturally to the taxonomic bent, with numerous gradations subcategorizable as alloforms of -emic categories roughly analogous to genera and their species.

Though taxonomy dictated the form that dialect studies took, the ultimate impetus has a much deeper source in human nature. History is replete with observations about dialect, going back at least three millennia in the Western tradition to the myth of Babel in *Genesis* 11: 1–9, whereby the Lord punished his ambitious subjects by 'confusing their speech, so that they will not understand what they say to one another.' Since Babel there has been a continuous tradition of astute comment on dialect differences which makes a long prelude to the institution of dialectology as a systematic classificatory enterprise. The English scholar Alexander Ellis remarked in 1875 that 'collecting country words is looked upon as an amusement, not as laying a brick in the temple of science' (quoted by Chambers and Trudgill, 1998, p. 15). Ellis's spirit thrives, and is evident today in word columns in newspapers, tourist pamphlets on the local 'twang,' stand-up mimicry in theaters, news features on slang, and in dozens of other ways. The discipline of dialectology appears to be the scholarly manifestation of this natural human curiosity about language variation.

Methods

Until recently, dialectology gave primacy to recovering the oldest extant forms of language. This deliberate bias colored its methodology at every point. Fieldworkers chose their subjects as a judgment sample of NORMs, an acronym for a prototype who was nonmobile, older, rural, and (predominantly) male. For instance, Edmont's 700 subjects, all ofwhom were rural, included only about 200 educated people and 60 women. The NORM prototype was purposeful. Lack of mobility guaranteed that their speech would be characteristic of their village. Harold Orton, director of the Survey of English Dialects (SED), England's nationwide survey on Gilliéronian principles for which data was gathered from 1950 to 1961, said, 'dialectspeakers whose residence in the locality had been interrupted by significant absences were constantly regarded with suspicion' (Orton, 1962, 15–16). Old age guaranteed that their speech would reflect a bygone era. Hans Kurath, director of the *Linguistic Atlas of New England* (LANE), part of the Linguistic Atlas of the USA and Canada that was begun in 1931 and still continues, declared that 'since most of the informants … are over 70 and not a few over 80, it would seem that we shall be able to establish the regionalism of the pre-industrial era of New England' (Kurath, 1949, p. 27). Rurality eliminated mobile urban dwellers who were likely to be exposed to other dialects and accents (Chambers, 2000). Males were targeted because their speech is less class-conscious than women's. As Orton put it, speaking about England, 'In this country, men speak vernacular more frequently, more consistently, and more genuinely than women' (1962, p. 15).

The basic methodology of traditional (Gilliéronian) dialect geography is to send trained fieldworkers to the locations where the subjects live in order to elicit specific items from the subjects guided by a standard questionnaire. The questionnaires are lengthy (Gilliéron's no less than 1500 questions, the SED about 1200, LANE about 700), with questions usually ordered by subject matter (flora and fauna, the barnyard, chores, etc.). Its purpose is to guarantee comparable data from all subjects. The fieldworker is expected to transcribe only the key word or phrase from the subject's response, no matter how long it might be. Labov summarized the method as 'a long question from the interviewer and a short answer from the subject' (Labov, 1971, p. 113).

These methods have been subject to criticism from commentators versed in social-science methodology, especially with respect to the reliability of the population sample and the validity of the data (for instance, Pickford, 1956). Obviously, NORMs constitute a rarefied minority when the majority population is exactly the converse – mobile, younger, urban, and female (Chambers, 1993, p. 134). But criticisms like these largely miss the point about the antiquarian bias that motivates the methods. Raven I. McDavid, a venerated fieldworker on the American project and an articulate apologist, defended the traditional methods with this succinct capitulation: 'There is a deliberate bias in the choice of communities – in the direction of smaller and often isolated places; there is a deliberate bias in the selection of informants, insistence on local roots and a statistically disproportionate sample of the older and less educated; there is a deliberate bias in the choice of items for the questionnaire, in the direction of the old fashioned rural society, the horsedrawn vehicle, the mule-powered plow and homemade bread. All of these biases are essential to the purpose of the investigation, to push the historical records as far back in time as possible' (McDavid, 1981, p. 71). Even as he articulated this defence, he inadvertently exposed the limits of the tradition at a time when modern technology had eliminated horsedrawn vehicles and social forces were inexorably diminishing the ranks of the uneducated and, indeed, rural society.

Structuralist Analyses

With the advent of Saussurean structural linguistics in 1916, language studies took a decisive turn in the direction of synchronic analysis. Taxonomy fell out of favor and intensionality gained adherents, at least in theory. However, dialectology clung to its autonomy, no more moved by structuralism than it had been by Neogrammarianism. Over the years, linguists made several attempts at integrating dialectology into linguistics. For instance, Uriel Weinreich (1954) proposed a level of analysis called the diasystem, which in

effect posited a level above the phonemic where 'diaphones' could be segmented into the actual phonemes in two (or more) specific dialect systems by means of interpretive rules. Weinreich speculated that speakers must use something comparable to a diasystem for comprehension when they interact with speakers of other dialects.

Later, with the development of generative frameworks, there were similar attempts at integrating dialectology. For example, Keyser reanalyzed traditional atlas data from the Atlantic coast of the USA by demonstrating that several vowel distinctions found in the painstaking tabulations for dozens of speakers could be generated simply by positing two phonological rules and 'accounting for the formation of new dialect groups through the geographical dissemination of rules' (Keyser, 1963, p. 313). Efforts like these gained few adherents, and they remained peripheral to the linguistic mainstream and had little impact on dialect studies.

More successful were the uses of atlas data in elucidating problems of historical linguistics. For instance, Hall (1943) used data collected in the *Sprachund Sachatlas Italiens und der Südschweiz* ([AIS] Jaberg and Jud 1928–40) to demonstrate the persistence of the old political boundary of the Papal States on patterns of dialect differentiation in twentieth-century central Italy. The purposes of historical linguistics were of course consonant with the intentions of traditional dialectology, although the exploitation of the latter by the former offered much greater potential than was actually realized. It did, nevertheless, establish a vital, if minor, tradition.

Decline and Rebirth

As post-Saussurean language studies continued to be dominated by synchronic linguistics and entered a period of considerable currency stimulated by the ideas of Noam Chomsky, the failure of dialectology to become integrated caused it to slip ever further into the periphery of language studies. By the middle of the twentieth century, scholarly activities had slowed and become relatively inconspicuous. By 1980, even dialectologists began to realize that reform was necessary. In the first book-length summation of the field, Chambers and Trudgill stated: 'one might well wonder what the future holds for dialect geography. There is no doubt whatever that the financing of research and publishing for large-scale surveys is a great problem, and there is also no doubt that capable and enthusiastic practitioners of the calibre of those who went before are difficult to find; but it seems most likely that both of these facts follow from another fact, namely, that dialect research has taken a new direction … It is probably safe to say that the future of dialect geography depends upon the ability of its practitioners to embrace and incorporate the concerns and perhaps the methodology of urban dialectology' (Chambers and Trudgill, 1980, p. 23).

Many aspects of dialect geography came under criticism when they were noticed at all, including the utility of the *Sprachatlas* as a medium for disseminating results. 'For whom are these expensive volumes designed?' Macaulay asked, and then he said: 'Far from being a visual aid the maps are probably a barrier to grasping the pattern of distribution and it seems very unlikely that anyone nowadays would attempt this kind of mapping. Given the sorting power of computers, basic information is much better stored in a form that is suitable to machine processing than in conventional map form' (Macaulay, 1985, p. 180).

With the founders gone, the rearguard reaction to these criticisms was muted. Starting in the mid-1980s, dialectology underwent a renaissance from which it would emerge as a vital and vigorous discipline with greater worldwide currency than ever before and, not coincidentally, greater intellectual depth. The sources were the antidotes identified in the two critiques above: the embracing of powerful new technology and the adaptation of more inclusive research methods.

Computerization

From its inception, dialectology had been burdened by an overabundance of data. Dialectology aspired to be, in Saussurean terms, a science of *parole*, that is, the study of language as a communal effusion, apprehended in actual speech events, imbued by and indeed mediating what Sapir called 'the apparent lawlessness of social phenomena' (Sapir, 1929, p. 166). But the profusion of data proved daunting, and the methods used in classic dialect geography came into being partly as devices for delimiting the effusion and subjugating its lawlessness, by focusing on a narrow, linguistically conservative population, restricting elicitation to a closed set of items, and transcribing only individual tokens from the flow of speech.

The development of tape-recording as a reliable, affordable technology in the 1950s provided a means for making a permanent record of the flow of speech. However, the immediate impact of tape-recording on dialectology was negligible, coming into use merely for recording traditional elicitation sessions and thus serving mainly to provide archival documentation of the practices of McDavid and other fieldworkers. The most innovative of all regional surveys, the *Linguistic Atlas of the Gulf States* (Pederson et al., 1986–92 [LAGS]), directed by Lee Pederson, made a significant advance by recording all its interviews so they could be transcribed later under laboratory conditions. Meanwhile, beyond the formal confines of dialectology, tape-recording was embraced as a liberating medium by a few linguists genuinely interested in studying vernacular speech. In this way, tape-recording stimulated the rise of sociolinguistics, an urban dialectology with methods and goals that bore little resemblance to dialect geography.

More significant technology for the revitalization of dialectology came with the development of computers as reliable data-handling devices in the late 1960s, and especially as affordable and accessible universal processors in the 1980s. As Kretzschmar and colleagues put it: '… the development of dialect studies, whether geographical or sociolinguistic, has always been hampered by a superfluity of data…. Even smaller surveys have had to settle for selective analysis of their data because the wealth of possibilities for analysis overran the editors' time and the human capacity for holding in the mind only so much information at once. Computers can help overcome these problems: they are wonderful tools for quickly sorting and matching pieces of information and for performing complex calculations on the results, and…. they are practically unlimited in their ability to store data' (Kretzschmar et al., 1989, p. v).

Many dialectologists recognized the computers' potential for relieving the perpetual problem of overabundance. No less important, many scholars recognized the enormous advantages that would accrue from the computerization of the classic databases of the ALF (Heap, 1997), SED (Ramisch, 1997; Elmer and Rudin, 1997), AIS (Goebl, 1993), and the others. Generalizations buried in lists and tables for many decades could be disinterred by judicious computation.

Dialectometry

A significant development directly attributable to computational processing is dialectometry, literally, the 'measure of dialect.' The word *dialectométrie* was coined by Pierre Séguy, director of the *Atlas Linguistique de Gascogne*, one of the regional surveys comprising the *Nouvel Atlas de la France*. Séguy hoped to replace subjective judgments on the occurrence of dialect regions by quantifying the Gascony data in such a way that the regions would be revealed objectively – in effect, they would reveal themselves. In the sixth and final volume of the Gascony atlas (Séguy, 1973), Séguy and his associates – *mes élévescamarades*, he called them – published a set of maps, which linked each of the survey sites to its nearest neighbors by a number representing the percentage by which the two sites differed with respect to the forms elicited there. Séguy conceived the percentages as an index for measuring the 'linguistic distance' between the two places. The analyst, by inspecting the distance indices, could draw inferences about dialect regions based on degrees of similarity and difference.

Though Séguy's methods now look primitive, restricted as they were at the time to univariate comparisons and handmade cartography, the numerical gradations across the maps rightly impressed many dialectologists as the first approximation of a visual analogue for the dynamics of dialect gradation in space. Since then, dialectometry has advanced to multivariate statistical programs and computer generated multidimensional displays that simultaneously compare all sites to one another. Dialectometry has become a generic term for all kinds of statistical dialect geography linked, as Goebl says, by a common goal: 'The preponderant aim of dialectometry consists in discovering, by the numeric combination of many low ranking patterns, higher ranking patterns which have remained hitherto hidden, in order to obtain a systematic insight into the problem of the basilectal management of space by HOMO LOQUENS' (Goebl, 1993, p. 277). Practitioners of dialectometry can be found around the world from Japan to Canada. The numerous research programs remain largely uncoordinated and partly incompatible, but in the next decades the consolidation of methods and goals will undoubtedly crystallize into a powerful branch of dialectology unimaginable in the first century of the discipline.

Sociolinguistic Dialectology

The other revitalizing impulse for dialectology is sociolinguistics, which had its effective beginning in the 1960s with the dissemination of William Labov's fountainhead studies in Martha's Vineyard and New York's Lower East Side (collected in Labov, 1972). Linguists began studying language variation with freer data-gathering methods, using larger and more representative subject samples, and they sought to understand its social significance with quantitative, acoustic and statistical analyses. The intellectual forebears of sociolinguistics, far removed from Linnaean taxonomy, were post-structural linguistics and the social sciences.

Dialect geographers, not surprisingly, did not immediately embrace the new currents, and it took a generation schooled primarily in sociolinguistics to recognize that the two disciplines were both, in essence, dialectologies. With hindsight, the rise of sociolin guistics can be viewed as a natural response to global social forces that have arisen since dialectology came into being, including urbanization, mobility of all three kinds – geographical, occupational and social – embourgeoisement, mass education and mass literacy. Those forces shrank the traditional domains of dialect geographers by reducing geographically isolated regions and socially isolated subjects to statistical insignificance in all the developed nations and beyond.

Observations of linguistic variation became refocused on social class, network, age, sex, ethnicity, and other social subgroups as well as region, and the systematicization of those observations required new sets of independent variables and new methods for tracking them. In the social context that came into existence a century after Warelius and Wenker, the remaking of dialectology as sociolinguistic dialectology was inevitable. As Chambers and Trudgill said, 'A decade or two ago, it might have been possible to think that the common subject matter of dialectology and sociolinguistics counted for next to nothing. Now we know it counts for everything. Dialectology without sociolinguistics at its core is a relic. No serious perspective on dialectology can grant urban research and variation theory less than a central role' (Chambers and Trudgill, 1998, p. 188).

One of the historical consequences of dialectology becoming sociolinguistic is that it has become an integral branch of linguistics. Like other branches of linguistics, its seminal works and formative investigations have been impelled and largely defined by specific issues, that is, by the need to develop or refine or refute particular hypotheses. The defining issues include these (discussed in Chambers, 1993), among others: (1) How do the changes dialectologists observe in progress reflect the changes that occur in the history of languages? (2) How, if at all, do the grand concepts of the sociology of language – concepts such as di glossia, language shift, heteronomy, linguistic legislation and planning – affect social interaction, or become encoded emblematically in sociolinguistic variants? (3) How do dialect features diffuse throughout regions, and how does such diffusion affect the linguistic behavior of people in the community? (4) What is the adaptive function of dialect and accent? This last question, in particular, can be posed as a kind of ultimate question for all dialect studies.

There is a long tradition that presupposes dialect and accent to be dysfunctional, starting with the Babelian myth. Dialectology in all its methodological and intellectual guises shows that, on the contrary, in every human society linguistic variation prevails and thrives. It is a profoundly human attribute that is essentially irrepressible. The large, open-ended questions of dialectology can only begin to find their answers in fine-grained, minute research into the social significance of linguistic

variation. The answers to those questions will ultimately elucidate the human language faculty. With that as its goal, dialectology constitutes a vital branch of modern linguistics.

Abstract

This article considers the origin and changing use of the notion of diaspora, showing how, despite its specific reference to the history of the Jews, it has now come to be used in understanding wider implications of international migration and transnationalism. How modern nation-states respond to the challenges and opportunities posed by diasporas is discussed. The different types and forms of diaspora, and the diverse ways in which the concept is now deployed are also identified.

Origins and Development

The word 'diaspora' is derived from the Greek word *speiro* (to sow) and the preposition *dia* (over). When applied to humans, the ancient Greeks thought of the word as signifying expansion through settlement. 'Diaspora' soon acquired a more brutal and catastrophic meaning. In the Greek translation of the Old Testament it was used to describe the forcible dispersion of the Jews. The destruction of the Temple in Jerusalem in 586 BC led to the enslavement and displacement of the key military, civil, and religious leaders of Judah and their exile in Babylon. This fate was held to be predicted in Deuteronomy (28: 58–68) where it is stated that people who disobeyed God's law would be scattered to all ends of the earth. There they would 'find no peace,' while they would additionally suffer 'an unquiet mind, dim eyes and a failing appetite.' 'Babylon,' then the capital of the Mesopotamian empire, became the code word for Jews (and later for Africans in the New World) signifying a place of loneliness and estrangement, where they were held in captivity.

This catastrophic meaning of diaspora, which may be described as the 'victim tradition,' was one that informed the historical and popular use of the term for nearly two millennia. Gradually, other groups saw themselves as victims of forcible dispersion in a manner similar to the ancient Jews and used the expression 'diaspora' as a self-description of their fate. Armenians, for example, allude to the period 1894–96 when their national movement was violently opposed by the Ottoman Sultan Hamid and some 300 000 Armenians were killed in Turkish Armenia. In 1915–16 'close to one million people' (Melson, 1992: p. 146), about half the Armenian nation, were either killed or died of starvation. Armenian scholars and activists have accused the Ottoman authorities of genocidal intentions, an interpretation that is generally accepted, although one that has been hotly disputed by successive Turkish governments. The subsequent dispersal of the Armenians to the United States, Iran, France, Lebanon, and other countries is now commonly described as a diasporic experience. The brutal Atlantic slave trade for New World Africans and the potato famine for the Irish are similarly considered to be the crucial traumatic events that triggered the creation of these other victim diasporas. For Palestinians, the birth of Israel is *al-Nakba* (the catastrophe), which impelled their dispersal and exile and continues to fuel their struggles for national self-determination.

The above examples have an apparent theoretical and experiential coherence. A tragedy perpetrated by a hostile exogenous force generates movement to a number of countries. But because the displacement was forced and the traumatic event so encompassing, collective folk memories are developed, the social group remains psychologically unsettled and socially marginalized, and a return movement gains some following. A number of conventional historians would wish to go no further with the idea of diaspora. However, from the 1980s, this relatively well-established meaning began to collapse. Many ethnic groups of varying histories defined themselves as 'diasporas,' or were so recognized by scholars or journalists. The decisive intellectual recognition of this new heterogeneity was marked by the launch of a journal called *Diaspora*, issued by the New York office of Oxford University Press in 1991 and edited by a US-based literary scholar of Armenian provenance. His opening manifesto was an impressive call for openness. The journal would be concerned with "the way in which nations, real but imagined communities, are fabulated, brought into being, made and unmade, in culture and politics, both on the land people call their own and in exile" (Tölölyan, 1991: p. 3). By 1998, the journal had published articles centrally identifying 34 ethnic groups as diasporas. Many hundreds of subnational, national, transnational, and religious groups are now more casually referred to as 'diasporas.'

Types of Diaspora

Natural scholarly caution would invite rejection of this profligacy. Yet, arguably, the pluralists have a good case. The paradigmatic example of the Jews, for example, shows that the communities abroad often arose from voluntary, not forced, movement, while the Babylonian experience can be characterized far more positively – as a place where new creative energies were released and challenging cultural encounters arose over a long period in a largely peaceful setting. Moreover, as has been mentioned, the original Greek meaning of diaspora allowed voluntary movement or even colonial settlement. Drawing on this etymology, it would be consistent, if unconventional, to refer to the British colonies in New Zealand, Australia, and Canada as comprising part of 'the British diaspora' – of an imperial, rather than victim, type.

In addition to the victim and imperial types, scholars have identified labor, trade, business, professional, religious, cultural, deterritorialized, and refugee diasporas, as well as intermediate forms such as incipient, asylum, and 'new' diasporas (Safran, 1991; Sheffer, 1995; McDowell, 1996; Van Hear, 1998; Cohen, 2008). These subtypes describe the predominant characteristic or characteristics of each diaspora, but cannot represent adequately the full complexity of each group in terms of its history, mixed motivations for emigration, or class and regional diversity. It is apparent, for example, that the 50 million 'Chinese overseas,' who have only recently been described as a diaspora, include people from different ethnic and linguistic backgrounds, whose origins lay in semifree 'coolie labor,' as well as those who migrated as entrepreneurs, traders, and skilled professionals.

Despite the new pluralism, there remain key differences between a diaspora and migrants in general. First, cultural, linguistic, religious, historical, and affective ties with the place of origin remain strong. Second, at least in theory, while emigration from 'an old country' involved a one-way ticket, assimilation to the 'new country,' the adoption of a local citizenship and language, and the public acceptance of local ways and customs, these common features of migration do not apply to a diaspora. As studies of a number of ethnic groups in the United States and elsewhere have shown, in culture and endogamous practices the old ways are more resilient than public ideology proclaimed. In these cases, group boundaries endure while strong and complete assimilation does not take place. Third, families and diasporic activists in the different places to which groups have been dispersed effect links to one other, thereby forming a transnational community.

Forms of Diaspora

In addition to typologizing diasporas by examining their broad characteristics, scholars have sought to classify the different 'forms' in which diasporas appear and how these map on to the understanding of the concept in different academic disciplines. A generally successful fourfold scheme has been proposed by Vertovec (1997) and modified in Vertovec and Cohen (1999). A fifth form has been added below:

1. The first category, usually advanced by economists and sociologists, is 'diaspora as social form,' alluding to the maintenance and development of transnational social organizations and networks, a collective identity and particular kinds of economic strategies. These strategies are closely linked to the idea of social capital, which allows those with a network of trust and social cohesion to fund investments, support enterprise, and promote collective social mobility through education and other means (Kotkin, 1992; Cohen, 2008).
2. The second form is 'diaspora as consciousness.' Cultural studies theorists as well as those working in the fields of ethnic and race relations found in the notion of diaspora a means of breaking free from the 'essentialist' discourse that previously informed the subject matter. Notions of what constituted ethnicity became more fluid, hybrid, and negotiated, and 'diaspora' was a way of representing how complexity and difference arouse as cultures traveled, interacted, and mutated (Clifford, 1992; Brah, 1996).
3. The third is 'diaspora as mode of cultural production.' Although closely related to the second, this form is used by anthropologists to show how social and cultural formations, as well as cultural objects, images, and meanings have leaped from their old locales and crossed national lines (Hannerz, 1996; Basch et al., 1994).
4. Fourth, 'diaspora as political orientation' has been considered by political scientists and international relations theorists. As noted below, such specialists concentrate on how the attachment to the politics of homeland can negatively and positively impact on the countries at both ends of the migration chain.
5. We need now to add a fifth form, namely, 'e-diasporas as connected migrants,' a notion advanced by digital specialists. Diminescu (2012: p. 452) argues that an e-diaspora "organizes itself and is active first and foremost on the Web." In so doing, she argues, an unstable collective emerges (as people switch on or exit) but, despite this constant renegotiation of the extent and nature of an e-diaspora, the connection is sufficiently dense and meaningful to disrupt the traditional rupture between 'home' and 'away' and between the different points (or edge nodes) of settlement.

Diasporas and Public Policy

For many countries, the goal of full integration was at the heart of the nation-building project. During the period of intense nation-building in the core European, South, and North American states a diasporic consciousness was either not sanctioned or firmly suppressed. The US state's motto 'Ex Pluribus Unum' provided an example of the prevailing preference for assimilation or the creation of a new national culture. However, under the impact of diverse and accelerating immigration a number of important nation states (Canada, the United States, the Netherlands, Australia, and the United Kingdom might be cited) lost their appetite and perhaps the capacity to assimilate immigrants to a single dominant political culture. By recognizing ideas of multicultural, multifaith, and multiracial societies, their political leaderships reversed their previous disapprobation of the retention of preimmigration ethnic identities.

Many policy makers and social commentators are relaxed about this development and see no incompatibility between a national and an ethnic affiliation. Others, including those from the progressive side of the political spectrum, are anxious that the painfully achieved democratic and secular order in societies such as the United States will be undermined by the recognition of diasporas. For the liberal historian, Arthur Schlesinger Jr. (cited Hu-DeHart, 1993: pp. 7–8), "The US escaped the divisiveness of a multi-ethnic society by a brilliant solution: the creation of a brand new identity. The point of America was not to preserve old cultures but to forge a new, American culture." Diasporas are seen as the reason why this idea has not been fully realized. For some commentators, diasporas foster religious zealotry, the international drugs

trade, political instability, and cross-border terrorism. The involvement of exile groups, like the Tamils, Kurds, Sikhs, or Afghans, in the political life of their homelands or in movements to create nation-states, has often created violent conflicts or embarrassing and difficult diplomatic and legal conflicts (Sheffer, 1986). By contrast, Shain (1999) argues that the democratic and liberal ways learned in the place of settlement are more likely to spread back into the countries of origin, with benign political effects for all parties.

The policies of the countries of origin to their diasporic communities abroad has only recently gained systematic discussion by diaspora scholars, in recognition that these states are increasingly important players in retaining and amplifying the links between 'home' and 'away.' Historically, countries like China and India were hostile to their overseas communities, seeing them as painful reminders of colonial days when their people could be seduced by labor recruiters offering indentures on European-run tropical plantations or, in the contemporary period, as 'brain-drain' migrants. India, China, and many other migrant-exporting countries now recognize that their diasporas can provide an important political lobby for advancing their countries' interests, a bridgehead for economic marketing of the home countries' goods, a means for acquiring transferable skills (e.g., in information technology) and, above all, a rich source for remittances and investment income.

So important have diasporas become to origin states that many have initiated a battery of initiatives to establish, reestablish, or maintain ties to homelands. As Gamlen (2008: pp. 840–856) shows, these include recognizing diaspora associations or founding them, granting a variety of civil, social, and political rights to nationals abroad, issuing specialized passports, allowing or encouraging dual nationality, providing emergency consular support, creating incentives to invest 'at home' and permitting tax holidays for the remittance of income and profits. Many countries have now created ministries, departments, or other units to service the needs of their diasporas and represent their concerns to other government departments. Examples of such units are the Institute for Mexicans Abroad, the Irish Abroad Unit, and Delhi's Ministry of Indian Overseas Affairs. The Philippines also has an expertly run, state-supported set of agencies (notably the Commission on Filipinos Overseas) that promote labor export on a vast scale, help to channel return income, and seek to protect their workers from exploitative employers abroad. The Commission additionally sponsors a 'Global Summit of Filipinos in the diaspora,' where 'D2D' (Diaspora to Development) initiatives in the arts, culture, education, philanthropy, medicine, and agriculture are encouraged and sustained.

Future of the Concept

The concept of diaspora has decisively escaped its historical confines in the Jewish experience and is now used in a variety of settings and for a variety of purposes. The enduring logic is that the term conceptually connects home and abroad. The conflicting claims on group loyalties have been given an added emphasis in an age of global networks and the changing role, some would argue the relative decline, of the nation-state as a focus for group identification. 'Diaspora' will remain as an important means of interrogating and exemplifying this tension. It will also provide a useful means of describing the enhanced role for cyclical, transversal, and intermittent international migration. The arrival of the Internet will both enhance the historical ties found within diasporas and, to some degree, change their character. A striking possibility is that e-diasporas might create new virtual homes, without the need for a territorial homeland.

Beyond these significant changes are other, more adventurous uses of the expression. For example, the use of 'diaspora' to describe all transnational religious communities and nationalities abroad is not always apposite. In some cases, such as the Jews, Parsis, and Sikhs, religion, ethnicity, minority status, and peoplehood are so closely interpenetrated that the description 'diaspora' is appropriate. However, 'Muslim diaspora,' which yields many hits on a Google search, undervalues the ethnic and national diversity concealed by the expression. Is the *Ummah*, one may further ask, coterminous with 'a Muslim diaspora'? Again, 'Indian diaspora,' an expression that is now in common and official use, elides the differences between the three principal faith communities (Hindu, Muslim, and Sikh) and ignores well-organized national minorities (like the Kashmiris), with potentially confusing effects. In addressing such problems, there may be some virtue in using the wider expression 'transnational communities' to include a number of different postnational and nonnational forms of sociality and association. Examples so categorized can be virtual Internet communities, business networks, Christianity, Islam, transnational social movements, and international professional associations. Within the rubric of transnational communities can shelter 'diaspora' as a particular form of ethnically defined community.

Despite this suggestion for self-limiting the term, it is clear that a number of scholars, particularly in the humanities, have abandoned the confines of ethnicity in their enthusiasm for the expression 'diaspora.' At the heart of this appropriation of the term is the idea that social marginalization (seen earlier in the failure of ethnic diasporas to fully assimilate) is a sufficient precondition for a formation of a diaspora. Motley and Henderson (2008) argue the global hip-hop movement is a diaspora as it transcends ethnic, linguistic, and geographical boundaries, while Patten and Sánchez-Eppler (2000) suggest that queer diasporas are formed as people move across literal and figurative boundaries. These are but two examples of the argument that diasporas are formed by real or symbolic marginality, chosen lifestyles, or mutually recognized cultural preferences. It is common ground that the Internet has facilitated some degree of cohesion within such groups.

There is little doubt that the elastic band holding the meaning of 'diaspora' together is getting slacker and slacker. As Brubaker (2005) has suggested, this can be seen as a conceptual dispersal, a movement into uncharted semantic, conceptual, and disciplinary spaces. He amusingly calls this tendency a 'diaspora diaspora.' To avoid this attenuation of meaning, some degree of self-restraint may prove necessary if the term is to retain its conceptual purchase. In other words, the future of the term may be imperiled by having been commandeered to serve too many discrepant purposes and its use to describe cognate, yet importantly different, phenomena.

Dichotic Listening and Language: Overview

Abstract

In this article, I provide a selective review of the history of dichotic listening and its use as an application in neuropsychology, both with regard to research and clinical work. The review traces the concept of presenting simple speech sounds, such as syllables or numbers dichotically, from its original use by Broadbent in studies of attention in the early 1950s, to the pioneering work by Kimura a decade later in her studies of hemispheric asymmetry, and to the present-day use of the dichotic listening procedure in research and clinical practice. The article reviews studies on both healthy individuals and psychiatric and neurological populations. In addition to behavioral studies, dichotic listening has also been used in functional neuroimaging studies to reveal the underlying neuronal circuitry of language at the brain systems level.

Brief History of Dichotic Listening Research

The British psychologist Donald Broadbent is credited as having been the first to systematically use a dichotic setup in his studies of how air traffic controllers managed to maintain attentional focus when they had to process flight bearings from several airplanes at the same time (Broadbent, 1956; see also Bryden, 1988; Kimura, 2011; Hugdahl, 2011 for historical overviews of dichotic listening research). Broadbent used a dichotic procedure with different auditory messages being sent to the right and left ear, requiring the subject to focus attention on either the left or right-ear message, as a way to simulate the real-life situation facing the air traffic controllers. It should be noted, however, that although Broadbent used a dichotic setup, he did not systematically investigate whether there was an asymmetry in how subjects were able to process the different messages in the right or left ear. In fact, if there was any interest in dichotic listening outside of an attentional framework it was not in asymmetry of the brain, but rather implications for the understanding of short-term memory. Bryden (1988) writes that Donald Hebb had suggested that Broadbent's findings of subjects' tendency to first report the set of stimuli in one ear and then proceed to the other ear, must involve some kind of short-term memory mechanism. The discovery that dichotic presentations of verbal stimuli produced an increased number of correct reports for items presented in the right ear is credited to Doreen Kimura, who in a seminal paper in the Canadian Journal of Psychology (1961a) found that patients with temporal-lobe pathology reported more items from the right ear than from the left ear. She followed up the 1961a findings on patients with a study on right-handed neurologically intact individuals published the same year (Kimura, 1961b; in fact the two papers appeared back-to-back in the same issue). Again the results showed that there were more correctly reported items from the right ear than from the left ear. In a personal recollection of the pioneering 1961-studies, Kimura (2011) writes: "I knew from animal research that the crossed pathways from the ear to auditory cortex predominate over the uncrossed, and in fact might occlude the uncrossed input where there was overlap (Rosenzweig, 1951; Tunturi, 1946). I concluded that the right-ear effect was due to the fact that in people also, the crossed auditory pathways were more effective than the uncrossed. This gave the right-ear input an advantage in accessing areas in the left hemisphere critical for speech perception" (p. 214). **Figure 1** shows a drawing of the crossing of the auditory pathways and the underlying neuroanatomical basis for the right-ear effect (adapted from Kimura, 2011; originally published in Kimura, 1967). The original electrophysiology work by Rosenzweig (1951) and the anatomical model proposed by Kimura in 1967 to explain the REA were later corroborated in both lesion studies (e.g., Sparks and Geschwind, 1968; Pollmann et al., 2002) and with advanced electrophysiology (e.g., Brancucci et al., 2005) and finally with neuroimaging techniques (Hugdahl et al., 1999). The study by Sparks and Geschwind (1968) was the first study to also show the importance of the corpus callosum for the REA. They tested a patient with commissurotomy in which the two

hemispheres were surgically separated by sectioning the corpus callosum. This patient showed an almost total REA, and a corresponding left-ear extinction effect, which then demonstrated the direct pathways for the right-ear stimulus and the indirect (callosal) pathways for the left-ear stimulus in the dichotic situation. This was later corroborated by Westerhausen et al. (2008) using diffusion-tensor imaging (DTI) technique. Others have, however, claimed that a neuroanatomical model does not take into account cognitive factors, e.g., attention that may also contribute to the REA (e.g., Hiscock and Kinsbourne, 2011; see also below under top-down modulations of the REA).

The right-ear effect that Kimura mentioned was called a 'right-ear advantage (REA)' by Shankweiler and Studdert-Kennedy (1967), and later abbreviated REA (e.g., Bryden et al., 1983; Hugdahl and Andersson, 1984). The next researcher to take up the thread of the right-ear effect was P.M. Bryden who suggested that the right-ear effect observed by Kimura could have been caused by an 'order-effect' since subjects were instructed to report the right-ear items first. He therefore counterbalanced the order of presentation, but the REA still prevailed despite controlling for any 'order-effects.' Bryden (1963) concluded that "The findings suggest that the auditory system is better organized for the perception of verbal material presented to the right ear" (Abstract, p. 103).

Asymmetry for Working Memory

It should be noted, however, that the original studies by Kimura and Bryden were not exclusively about laterality for speech perception, but also contained elements of working memory. This was evident from the stimulus paradigms used in these studies. In both the Kimura and Bryden original studies, series of 3, 4, or 5 pairs of digits were presented dichotically, i.e., one digit in the right ear and another digit simultaneously in the other ear. The instruction to the subject was that he/she had to later recall which digits had been presented. Thus, the situation was to first listen to 6, 8, or 10 digits in sequence, and immediately after report as many digits that was possible, while the experimenter noted how many were reported that had been presented in the right ear and how many were reported that had been presented in the left ear. However, this situation requires the subject to keep the nonreported, but recalled, items in the working memory buffer for its turn to be reported. Thus, the original studies also pointed to the fact that working memory for verbal stimuli interacted with the perception of the same stimuli to produce a laterality effect. Much later, Penner et al. (2009) explicitly studied the interaction of laterality for speech sound perception and working memory by having subjects to listen to three-, four-, or five-letter pairs i.e., using the same working memory load as in the original studies, but with different stimuli (spoken letters rather than spoken digits). The results are shown in **Figure 2**, which reveals that as the working memory load increased from three to four stimulus-pairs the REA also increased, while it leveled off when the working memory load increased further to five-letter pairs. The results in the study by Penner et al. (2009) followed the original working memory effect in dichotic listening reported by Bryden (1963) when controlling for the order of report from either the right or left ear.

The Consonant-Vowel Syllables Paradigm

In 1967, Donald Shankweiler and Michael Studdert-Kennedy at the Haskins Laboratories (see also Studdert-Kennedy and Shankweiler, 1970) asked the question at which level of speech processing the asymmetry the right-ear effect occurred, and if the REA was modified by the phonetic features of the stimuli. To be able to study these questions empirically they introduced a new paradigm, the consonant-vowel (CV) syllables paradigm. This paradigm consisted of pairwise presentations of CV-syllables based on the six stop-consonants /b/, /d/, /g/, /p/, /t/, /k/ that were paired with the vowels /a/, /e/, /i/, /æ/, and /u/. With this paradigm, it was possible to study the relative contribution of the consonants and vowels separately, by analyzing the different phonetic contrasts made up of combinations of the consonants and vowels. The instruction to the subject was to verbally report which syllable he/she had perceived after each trial. Shankweiler and Studdert-Kennedy (1967) included 15 right-handed members of the laboratory staff, and included also a test with only the steady-state vowels that were presented dichotically, a different vowel in each ear. A significant REA was observed only for the consonants, but not for the vowels (later replicated by Hugdahl & Andersson, 1984), indicating that the REA may be more of a perceptual effect for the identification of the initial phonological information in a syllable. Shankweiler and Studdert-Kennedy (1967) summarized the strong laterality effects they observed for the superiority for the right-ear items such that: "This strongly suggests that left hemisphere dominance in speech perception operates at the level of speech sound structure, [and that] the effect can be demonstrated when only a single pair of

syllables is presented on each trial indicating that it pertains to the registration of the stimuli and not only their retention." (p. 62). Thus, the study by Shankweiler and Studdert-Kennedy (1967) set the record straight that the REA was not a memory retention artifact, but a direct consequence of the phonetic features of the speech sound. Moreover, the effect was based on the energy release of the initial consonant segment of the CV-syllable, but relatively insensitive to the manipulation of the following vowel sound. The CV-syllables paradigm soon became very popular in research on hemispheric asymmetry and a search through PubMed and ISI Web of Knowledge data bases show that more than 2000 articles have used a CV approach in studies of auditory laterality. A paradigm that has been as popular as the CV-syllables paradigm is the fused-rhymed paradigm (Wexler and Halwes, 1983), which is similar to the CV-syllables paradigm except for the important distinction that the two sounds presented at the ears fuse into a coherent perceptual unit. A characteristic of the fused-rhymed paradigm is that although subjects subjectively report that they hear 'only one sound,' they report this to be the right-ear item.

Before proceeding with other studies that followed in the wake of the pioneering studies by Kimura, Bryden, and Shankweiler and Studdert-Kennedy, two factors that have been related to hemispheric asymmetry and dichotic listening should be mentioned, namely effects of handedness and sex differences.

The Effect of Handedness

The CV distinction as reported by Shankweiler and Studdert-Kennedy (1967; Studdert-Kennedy and Shankweiler, 1970) was later corroborated by Hugdahl and Andersson (1984) who contrasted the six stop-consonants with the vowels /a/, /i/, /u/. When analyzing the errors made for the different consonants and vowels respectively, they found significant differences for the consonants, depending on the ear of presentation, but not for the vowels. Interestingly, Hugdahl and Andersson (1984) also included a group of left handers, and found a reduction of the REA in the left-handed group, measured as fewer errors for the left-ear input compared to the left-ear input. Hugdahl and Andersson (1984) concluded that the CV-syllables dichotic listening paradigm "allows for the separation of left- and right-hemisphere dominance for right- and left-handed subjects" (p. 141). Later research has however concluded that the CV-syllables dichotic listening paradigm does not discriminate right- from left handers (e.g., Sommer, 2010 for a recent review), which would be expected considering that about 70% of left handers have language in the left hemisphere equal to right handers (Satz, 1973; Springer and Deutsch, 1989).

The Effect of Sex

Studdert-Kennedy and Shankweiler did not report on the sex of their subjects, only that they were right handed, and Hugdahl and Andersson (1984) only included males. Thus, it was not clear from the early studies if sex had an effect on performance on the CV-syllables paradigm and on hemispheric asymmetry in general. Although several early studies on hemispheric asymmetry and laterality, using different tasks and paradigms, both auditory and visual, had shown that males were superior on visuospatial tasks, while females were superior on verbal tasks (e.g., Harris, 1978; Levy, 1971), there were also studies failing to report significant sex differences (e.g., Hannay and Boyer, 1978; see also McGlone, 1980 for review). The first systematic review of sex differences on tasks measuring hemispheric asymmetry (Voyer, 1996) showed modest overall effects of sex, accounting for a small proportion of the variance. When it comes to sex differences in performance on a dichotic listening task, the data essentially show the same picture, the sex difference is either marginal or absent. Two recent meta-analyses (Voyer, 2011; Sommer et al., 2008; Hiscock and MacKay, 1985) both showed that sex differences in dichotic listening performance accounted for only about 1% of the total variance, with no significant differences between the sexes for the REA. These findings were recently followed up by Hirnstein et al. (2012) in the largest sample of males and females so far ($N = 1782$) where they analyzed the ear advantage scores separately for males and females, including children, young adults, and old adults. The results showed that sex differences in dichotic listening are age-dependent such that male young adults had a greater REA than young female adults. The results from the Hirnstein et al. study are shown in **Figure 3**.

Handbook of Dichotic Listening, 1988

After the initial studies which showed that the REA was a robust empirical phenomenon, replicable in many contexts and situations, there was a surge of studies applying dichotic listening to almost every phenomenon thinkable in research on hemispheric asymmetry. This produced a well of interesting findings, summarized in the volume *Handbook of dichotic listening*, Edited by Kenneth Hugdahl, and Published by Wiley and Sons, UK in 1988. These studies also created an optimism that dichotic listening could provide answers to outstanding questions regarding how the two hemispheres of the brain functioned, not the least in the clinical domain. For example, it was believed that dichotic listening could replace invasive methods, like the Sodium Amytal test (Wada and Rasmussen, 1960) for the identification of side of language in patients with epilepsy undergoing surgical treatment.

Clinical and Developmental Applications

The different chapters in the Handbook of dichotic listening (Hugdahl, 1988) showed that dichotic listening at that time had diversified into understanding not only the functioning of the two cerebral hemispheres when it came to laterality for speech and speech perception, but also applications to a wide range of disorders where these functions would be expected to be compromised. This was particularly true for studies of children with various forms of language disorders, like dyslexia (Bakker and Kappers, 1988), learning and reading disability (Obrzut and Boliek, 1988), and cognitive development in children (Hiscock and Decter, 1988). There were also chapters on the application of dichotic listening to psychiatric and

The figure shows the frequency of males and females split for different age groups and for magnitude of the laterality index (LI). An LI of '0' indicates no difference for the right- and left-ear scores, an LI of +100 indicates 100% REA and an LI of −100 indicates 100% left-ear advantage. neurological disorders, like depression (Bruder, 1988), schizophrenia (Nachshon, 1988), Sodium Amytal studies of patients with epilepsy (Strauss, 1988), split-brain patients (Sidtis, 1988), and correlates with brain lesion findings (Eslinger and Damasio, 1988). A general conclusion from reading these applications was that dichotic listening was a valuable noninvasive measure of abnormality of the laterality of speech. However, these early clinical findings also prompted a surge of interest in both hemispheric asymmetry in general and dichotic listening in particular, with very high expectations of what a noninvasive measure could achieve of data. When dichotic listening results did not completely match invasive data, as e.g., when matching the size of REA with aphasia data, people started losing interest in the field, not considering that no neuropsychological measure or test ever match lesion data on that level of matching.

Bottom-Up Modulation of the REA

An important question that was asked after the initial studies was the degree to which it could be, and was, modulated by other factors than laterality, and how hemispheric asymmetry interacted with those factors to modulate the REA. The modulation of the REA can be studied from two perspectives, one is the modulation as a consequence of the characteristic of the subject being tested, e.g., whether children show different degrees of the REA than adults, or if certain disorders affect the REA in a specific way, e.g., if dyslexic individuals perform different on a dichotic listening task than normal-reading individuals. The other perspective on how the REA is modulated is as a consequence of the stimulus characteristics, e.g., voicing and timing of the syllable sounds that are presented to the subject. With regard to the first kind of modulation, Hugdahl et al. (2001) showed that the REA is present at an early age, actually before reading, and is as such a feature of hemispheric asymmetry for language in a very basic sense. When it comes to studies of dyslexia and reading disorders, Obrzut and colleagues (see Obrzut and Boliek, 1988; Obrzut and Mahoney, 2011) used a CV-syllable dichotic listening paradigm to study the phonetic aspects of reading impairment in children with dyslexia and other language-related problems. This is in line with what Obrzut and Boliek already in 1986 reported of a reduction of the REA, or a tendency for a left-ear advantage (LEA) in learning- and reading-disabled children, see also Satz and Sparrow (1970) for an even earlier study in reading-disabled children. Such findings would then support a notion that reading disability is related to impaired phonological processing and phonological awareness (Høien and Lundberg, 2000), or reduced ability for low-level auditory discrimination (cf Tallal and Piercy, 1973). Another finding was from studies being conducted by Bakker and his colleagues in the Netherlands (e.g., Bakker, 1970; Bakker and Kappers, 1988), which showed that the development of the ear advantage and the REA was delayed in dyslexic children compared to normal-reading children. In still another series of studies Cohen et al. (1992) found that the REA was modulated not only by reading impairment and dyslexia in general, but children with auditory as compared to visual dyslexia showed greater reduction of the REA. A later study by Helland et al. (2007) found that the REA in dyslexic children was also modulated by how severe the disorder is, such that children

diagnosed with a reading disorder requiring special education training showed a greater reduction in the REA than children following regular classes. See **Figure 4**, for example, of the effect of how the need for special education training affects the REA. As can be seen in **Figure 4**, children with a dyslexia diagnosis and in need of special education training compared to children where such training was not considered necessary revealed a significant reduction of the REA. The REA may therefore have clinical value as a complementary diagnostic tool.

All in all, studies of dyslexia and reading impairment have shown that children with reading impairment and dyslexia show an aberrant laterality displayed as reduced phonetic discrimination and abnormal REA.

With regard to modulations of the REA as a consequence of the stimulus characteristics, Berlin and colleagues reported a series of intriguing studies in the 1970s (summarized in Berlin, 1977) on the effects of amplitude (intensity) and phase (time) shifts of the dichotic signal in the right versus the left ear. Berlin manipulated the two signals of the dichotic pair by increasing the intensity of, e.g., the right-ear syllable relative to the left, and vice versa, and noted how performance on the task varied. He also varied the relative timing of the onset of the two signals such that either the right or the left syllable trailed the other by a few ms, and noted how time differences affected the REA. The results by Berlin et al. were that when the right-ear signal lagged behind the left-ear signal by 15–30 ms, the REA was increased, and vice versa if the left-ear signal lagged behind the right-ear signal, thus showing a kind of feed-forward effect such that the signal arriving later had a greater effect on the ear advantage. From these studies, it is clear that the REA is modified and modulated by both amplitude and phase shifts of the two syllables in the dichotic pair. The early studies by Berlin and colleagues have later been followed up by Hugdahl and Westerhausen (e.g., Hugdahl et al., 2008; Westerhausen et al., 2010; Falkenberg et al., 2011) where they gradually increased the intensity of the syllable in either the right or left ear in steps of 3 dB at a time (Hugdahl et al., 2008). The results are shown in **Figure 5**, and revealed a linear increase in the magnitude of the REA when the right-ear signal was increased, and a corresponding linear decrease when the left-ear signal intensity was increased.

What is interesting from **Figure 5** is that the REA was shifted to LEA when the intensity of the left-ear signal was increased 6 dB above the level of the right-ear signal. Thus, the REA could therefore be said to withstand a sound pressure intensity difference of 6 dB, making it possible to express a cognitive concept (REA) in physical terms (dB). In later experiments, the same research group has found that the REA withstands up to a 9 dB difference favoring the left-ear signal, depending on the context in which the test is conducted.

A third kind of stimulus manipulation is voice-onset-time (VOT), also called voicing, which means comparing syllable pairs with voiced (/ba/,/da/,/ga/) versus unvoiced (/pa/,/ta/, ka/) syllables, corresponding to short (~20 ms) versus long (~70 ms) VOTs. The REA is sensitive to the VOT features of the dichotic pair such that having an unvoiced syllable in the right ear and a voiced syllable in the left ear produces a stronger REA than having equally voiced syllables in either ear. Interestingly, a voiced syllable in the right ear and an unvoiced syllable in the left ear produce LEA in adults (Rimol et al., 2006). Thus, it is obvious that the REA is modulated by both amplitude and phase shifts of the signals making up the dichotic pair. Özgören et al. (2012) put the two features together to investigate the relative contribution of amplitude- and phase shifts when the two features are in conflict, such as when increasing the intensity of the right-ear signal, but having the left-ear

signal presented 10 ms before the right-ear signal. Overall, the results of the Özgören et al. (2012) study showed that amplitude shifts favoring the right ear had a greater effect on the REA than corresponding phase shifts, while phase shifts favoring the left ear were found to have a greater effect on the LEA than corresponding amplitude shifts. In addition, it was found that phase shifts favoring the left ear had a greater effect on the LEA than corresponding phase shifts favoring the right ear had on the REA. The results of simultaneously manipulating amplitude and phase of the syllables in the dichotic pair is seen in **Figure 6**.

In contrast to the findings by Berlin and colleagues, Özgören et al. (2012) found that the REA was increased for syllable pairs where the right-ear syllable had an earlier onset, and vice versa for the LEA to syllable pairs where the left-ear syllable had an earlier onset. Recall that Berlin et al. (reviewed in Berlin, 1977) found that the REA was increased to syllable pairs where the right-ear syllable trailed the left-ear syllable,

and vice versa. The difference in results could be due to that the subject in previous studies was instructed to report both syllables in the dichotic pair, while Özgören et al. (2012) instructed their subjects to only report one syllable of the pair (the one perceived most clearly).

Top-Down Modulation of the REA

A completely different kind of modulation of the REA is from a top-down, or cognitive, perspective, e.g., when instructing the subject to focus attention to either the right- or left-ear stimulus of the dichotic pair (Bryden et al., 1983; Hugdahl and Andersson, 1986), or have another cue-stimulus presented in either the right or left ear a few hundred ms before the CV-syllables are presented, and instruct the subject to report the syllable in the same ear as the cue was presented in (Mondor and Bryden, 1991). In both of these situations, the aim is to induce a top-down cognitive strategy to focus attention on either syllable and then for the Experimenter to record the effect this has on the REA. The two procedures differ, however, in that in the first example, attention is shifted to one side for a block of trials, until the subject is instructed to shift attention to the other side. This was labeled as 'the forced-attention' paradigm by Hugdahl and Andersson (1986). In the second example, attention is shifted to either the right or left side on a trial-by-trial basis, since the subject cannot know which side he/she is expected to shift attention to on a give trial until the cue-stimulus is given (typically a brief tone), see e.g., Mondor and Bryden (1991). Top-down procedures go back to the use of shadowing approaches where the subject is instructed to shadow a continuous message in one ear while another message simultaneously is presented in the other ear (Cherry, 1953).

The 'Forced-attention' Paradigm

In the following, I will describe studies using the 'forced-attention paradigm' as it was developed by Hugdahl and Andersson (1986) since this is one of the most widely used variants of top-down REA modulation. A detailed description of the 'forced-attention' paradigm is at the end of manuscript for anyone interested in using the paradigm in empirical research, including instructions how to obtain a copy of the paradigm. Top-down manipulations were introduced into asymmetry research as a result of laterality studies by Marcel Kinsbourne (e.g., 1970; see also Hiscock and Kinsbourne, 2011 for an updated account of the attentional model in research on auditory laterality) that the processing differences for language seen between the right and left hemispheres could be due to a default attentional bias to process events happing in one half field of sensory space. Kinsbourne suggested that the REA may be caused by a kind of hemisphere preactivation mechanism of the left, language dominant, hemisphere in a language processing situation caused by attention bias to that side. Part of this suggestion came from studies of hemispace neglect where patients with localized lesions to the right parietal lobe revealed a deficit in processing events occurring the left hemispace (see Heilman and Valenstein, 1972; Heilman and Van den Abel, 1980; see also Heilman, 1995 for a review). It may be interesting to note that Oxbury et al. already in 1967 in a paper in Nature suggested that the ear advantage in dichotic listening may be caused by an attentional bias toward the right ear, and that the effect is not because of an effect of hemisphere dominance. Satz (1968) wrote a response letter to Nature where he presented new data and argued that Oxbury et al. (1967) were mistaken, and added: " …this conclusion is misleading, that it ignores central nervous system mechanisms which are probably associated with the asymmetry, and that the conclusion is inconsistent with experiments which have controlled for order-effects and have found a right ear superiority" (p. 277). Others have later (e.g., Pollmann, 2010) also pointed out that attention could not explain the findings in the 'forced-attention' paradigm introduced by Hugdahl and Andersson (1986) since in this situation the subject is asked also to pay attention to the nondominant left ear, which would not be part of an in-built bias to always shift attention to the left side in hemispace. Instructing the subject to pay attention to either the right or left syllable, and to only report from that side has nevertheless profound effects on the ear advantage. As expected, reporting only from the right ear increases the REA while reporting only from the left ear produces LEA in healthy adult individuals. In the initial studies, Bryden et al. (1983) and Hugdahl and Andersson (1986) it was believed that instructing the subject to half of the time report from the right ear and half of the time to report from the left ear would control for any unwanted effects of attention. Thus, attention was seen as an artifact, confounding a true laterality effect. Asbjørnsen and Hugdahl (1995) and Hiscock et al. (1999) found, however, that the different results for the right and left ear focus could be due to a more general cognitive factor, i.e., that attention was an integrated aspect of auditory laterality. At this time, it was however still believed that the active factor in modulating the REA as a consequence of instructions of side of reporting focus was attention. Later both Hugdahl (e.g., Hugdahl et al., 2009) and Hiscock and Kinsbourne (e.g., 2011) suggested a two-stage model with bottom-up and top-down processing. Hiscock and Kinsbourne (2011) argued that top-down manipulations only help in providing information about localization of signals, but not for the processing of the signal. Hugdahl, on the other hand, argued that the top-down manipulation, depending on which side is attended to, provides information about two fundamentally different modes of cognitive processing. Hugdahl et al. (2009) reviewed the dichotic listening literature on clinical patients, particularly patients with schizophrenia, and found it puzzling why these patients could not perform the condition with instruction to focus attention on the left-ear syllable (labeled 'forced-left' condition), while they performed normal when instructed to focus attention on the right-ear syllable (labeled 'forced-right' condition). It was moreover clear that healthy individuals also struggled more with the 'forced-left' instruction condition than with the 'forced-right' instruction condition, although they could switch to LEA, which the patients could not. Performance data for healthy individuals and patients with schizophrenia are shown in **Figure 7**.

From the schizophrenia and other clinical data, Hugdahl et al. (2009) describe the process that led them to the conclusion that the 'forced-right' and 'forced-left' instruction

Figure 7 Mean correct reports for the right and left-ear signal in the three 'forced-attention' instruction conditions, nonforced (NF), forced-right/(FR), and forced-left (FL), split for healthy individuals and schizophrenia patients.

conditions reflects different cognitive processes, or different degrees of different cognitive processes.

> We now believe that instructions to focus attention on the right or left ear stimulus induces different degrees of cognitive conflict and a corresponding need for cognitive control strategies. We have below described the process that brings us to this conclusion. The puzzle occurred when interpreting the results in two previous studies from our laboratory (Hugdahl et al., 2003; Løberg et al., 1999) with the 'forced-attention' dichotic listening paradigm (Hugdahl and Andersson, 1986) where it was found that patients with schizophrenia could not modulate the REA when instructed to focus attention on and report only the left ear stimulus, while they were able to modulate the REA when instructed to focus on the right ear stimulus. Healthy control subjects could easily perform both tasks, that is, they increased the REA when instructed to focus attention on and report the right ear stimulus, and reduced the REA, shifting to a LEA when instructed to focus attention on the left ear stimulus. A clue to an explanation of the selective FL effect seen in the patients as an example of cognitive control may be the fMRI study by Thomsen et al. (2004; see also Hugdahl et al., 2000; Jäncke et al., 2001) where it was shown that healthy subjects uniquely showed activation in the left prefrontal and anterior cingulate cortex areas when the BOLD activation images acquired during the FL task were contrasted with images obtained during the FR task, while the reversed contrast showed no remaining significant activations…. Considering that the prefrontal and anterior cingulate cortex have been linked to increased cognitive load, as seen in executive and other cognitively demanding tasks (Duncan and Owen, 2000), it could be argued that the FR and FL attention situations differ in the degree to which they reflect cognitive control (p. 3–4).

Brain Correlates of the REA

The underlying neuronal circuitry for the REA, which would also validate any theoretical model of the REA (e.g., Kimura, 1967; Pollmann et al., 2002) could be studied with functional neuroimaging methods like positron emission tomography (PET using radioactive ^{15}O, or functional magnetic resonance imaging (fMRI)). The first PET imaging study with CV-syllables was published by Hugdahl et al., 1999, using the ^{15}O-PET method. Subjects listened to the standard CV-syllables (see Appendix) while in the PET scanner and had to press a button placed on the chest whenever they detected a predetermined target syllable, thus the paradigm in the PET scanner deviated somewhat from the standard paradigm in that a target-detection procedure was used (see Clark et al., 1988 for a description of dichotic target-detection variants). As control stimuli, musical chords were presented, also dichotically, from three different instruments. The results are shown in **Figure 8**, and reveal significant bilateral activations in the superior temporal gyrus, with a significant leftward asymmetry when directly comparing the left minus the right side.

The corresponding activation for the musical chords showed a rightward asymmetry in the same region in the temporal lobe. The results thus confirmed previous behavioral results, and also the theoretical assumptions regarding the underlying neuronal pathways for the REA. The findings by Hugdahl et al. (1999) were replicated by van den Noort et al. (2008) who used fMRI, with superior spatial resolution and where the subject was instructed to give a verbal response after each syllable-pair presentation. Thus, the Van den Noort et al. (2008) study is so far the neuroimaging study that best resembles the standard behavioral paradigm, using verbal responses. The results replicated the basic asymmetry in the superior temporal gyrus reported in the Hugdahl et al. (1999) study, again confirming the specialization for processing of a phonetic stimulus (CV-syllable) in the left hemisphere. Van den Noort et al. (2008) also applied a conservative statistical procedure in that they used a probability mapping statistics,

showing only activated areas that succeeded a threshold of 80% (or 60%) of all subjects showing significantly activated in the same region of interest in the superior posterior region of the left temporal lobe.

Although the study by Hugdahl et al. (1999) was the first functional neruroimaging study using a dynamic imaging method, and with CV-syllables, Coffey et al. (1989) used a blood flow technique with inhalation of a radioactively tagged nobel gas, ^{133}Xenon, which would be distributed with the blood flow in the brain. The stimuli in the Coffey et al. (1989) study were however a pitch-discrimination task where the subject had to discriminate between the high and low pitch of tones presented dichotically, e.g., a high pitch tone in the right ear and a low pitch tone in the left ear. Thus, the task in the Coffey et al. study was not really a study of dichotic listening and hemispheric asymmetry for language, but for auditory processing and pitch processing. The results showed an asymmetry-effect in that activation was higher in the temporal lobe contralateral to the target stimulus of the dichotic pair.

Summary and Conclusions

In this article, I have summarized some trends in the history of dichotic listening research from the original studies by Kimura (1961a,b) to more recent studies using PET (Hugdahl et al., 1999) and fMRI (Van den Noort et al., 2008) to reveal the underlying neuronal circuitry. I have also shown how the REA is modulated and influenced by both bottom-up perceptual and top-down cognitive factors, and that this make the dichotic listening paradigm a much more dynamic and wide-ranging measure for the study of complex perceptual-cognitive asymmetry interactions with consequences for the understanding of cognitive deficits and impairments in clinical groups, like schizophrenia and brain lesion patients. I also show how dichotic listening may be an important vehicle to understand language development and language-related disorders, like dyslexia and other forms of learning disabilities. It may be relevant in this context to remind oneself of the conclusion in the introduction paper in the 50 years anniversary special issue in the *Journal Brain and Cognition* (Hugdahl, 2011), that "auditory laterality and dichotic listening will be an important field of study and method in neuropsychology and related fields of research and in the clinic…also in the next 50 years" (p. 213). Thus, despite unwarranted criticism that dichotic listening has outplayed its role in neuropsychology, recent advances with applications to the clinical domain, and with the introduction of top-down manipulations to study ever more complex brain-behavior interactions, dichotic listening is "still going and going and…" (Hugdahl, 2011, p. 211).

Appendix

In the following the 'forced-attention' paradigm is described as it is used in our laboratory, for the reader who wants to implement the paradigm for own research. The paradigm runs as an application in the E-prime programming platform (Psychology Software Tools, Inc., http://www.pstnet.com/eprime.cfm). A copy of the E-prime dichotic listening application and a manual describing how to use the paradigm and score the data can be obtained by sending an e-mail to Kenneth Hugdahl (hugdahl@psybp.uib.no). The manual also contains normative data for comparisons based on 1800 healthy subjects, aged 7–89 years, males and females, right- and left handers.

The 'Forced-Attention' Dichotic Listening Paradigm

The paradigm consists of series of presentation of CV-syllables via headphones to the subject. The stimuli are the six stop-consonants /b/, /d/, /g/, /p/, /t, /k/ that are paired with the vowel /a/ to form six dichotic six CV-syllable pairs of the type /ba/ – /ga/, /ta/ – /ka/ etc. The syllables are then paired with each other for all possible combinations, thus yielding 36 dichotic pairs, including the six homonymic pairs. The stimuli are natural speech, spoken by a male. The homonymic pairs are not included in the statistical analysis, but just as catch trials to ensure that the subject has understood the instructions. The maximum number of correct reports is thus 30 for each ear/instruction condition (nonforced, NF), with no instruction, forced-right, FR, instruction to focus on the right ear, and forced-left, FL with instructions to focus on the left ear. Mean duration is 350–400 m and the intertrial interval is ~4 sec, during which the subject orally respond, which syllable he/she has perceived on the previous trial. The syllables are read through a microphone and digitized for later computer editing on a standard PC using state-of-the-art audio editing software (SWELL, Goldwave, CoolEdit). The syllables are recorded with a sampling rate of 44 000 Hz and amplitude resolution of 16 bit. After digitization, each CV-pair is displayed on the PC screen and synchronized for simultaneous onset at the

first identifiable energy release in the consonant segment between the right and left channels. The stimuli are played to the subject using digital play-back equipment, connected to high-performance headphones, with intensity between 70 and 75 dB. The subject is told that he/she would hear repeated presentations of the six CV-syllables (ba, da, ga, pa, ta, ka), and that he/she should report which one he/she heard from the six possible syllables after each trial.

Dictatorship

Abstract

Before the modern period, the term 'dictatorship' was employed to signify a temporary suspension of a constitution, allowing one person to assume unlimited power in order to effectively respond to some crisis that threatened the integrity or the political survival of a community. By the Middle Ages in Europe, and the institutionalization of hereditary dynasties in East and South Asia, rulers who exercised unlimited powers were identified as 'emperors,' 'monarchs,' 'despots,' or 'tyrants.' By the beginning of the modern period, the term 'dictatorship' was reintroduced and applied to those systems in which constitutional constraints on governmental powers were suspended and unlimited power was transferred, usually, to a single individual. After the termination of the First World War, a new class of modern dictatorships emerged, characterized by 'vanguard parties,' 'charismatic leaders,' formal ideologies that served to legitimate self-selected minority rule, and security and control infrastructures capable of dominating entire populations. Out of that class of dictatorships a subset of regimes appeared that has been identified as 'totalitarianism.' Those regimes, because of their exclusive control over entire nations, and their conviction in their own imperative moral responsibilities, have undertaken the mass-murder or genocide of millions of innocents in the pursuit of political ends, for example, 'the purification of the race,' or the success of the international 'proletarian revolution.' Some of these regimes may have survived into the twenty-first century.

The term 'dictatorship' is one of Roman derivation, and originally signified the temporary suspension of constraints on governmental power and its unlimited transfer to one person. Among the Romans, there was provision for a temporary suppression of citizen rights during times of crises, and the equally temporary transfer of unlimited power, to a person chosen by the Senate and appointed by the Consul. At the end of a specified period – usually 6 months – the person so endowed, the dictator, surrendered power, and citizen rights were restored. The period of emergency stewardship was then duly reviewed, in accordance with constitutional requirements. During instances of emergency, over three centuries of republican constitutional rule, Rome appointed 88 dictators in conformity with law.

Following the rule of Julius Caesar, who exercised dictatorial powers for an unconstitutional length of time, the institution disintegrated and rulers assumed extra-constitutional powers in permanence. Rather than a traditional dictatorship, such rule took on the properties of what might more appropriately be called 'autocracy,' 'despotism,' or, perhaps, 'tyranny.'

Throughout the Middle Ages and more modern times in Europe, as well as during the institutionalization of dynastic rule in East and South Asia, 'autocracies' tended to be regularized through the agency of hereditary right – providing for succession without recourse to violence. Emperors, kings, and sultans could, and frequently would, allocate powers to 'noble' subordinates through a relatively well-articulated, rule-governed process. At times, as was the case in the rights embodied in the Magna Carta, some substantial rights were accorded to subordinates.

The Modern Period

With the decline of the Middle Ages, it became increasingly common that adventurers would seize power in emerging city-states and principalities, and rule as despots or benevolent autocrats. The term 'dictatorship' was rarely, if ever, employed to identify such rule until the commencement of the modern period.

In regions such as Latin America, the term came into increasing vogue after the liberation from Spanish colonialism, irrespective of the fact that the ideal, throughout Central and South America – influenced by the North American model – was constitutional democracy and political stability. The basic charters of most of the nations of Central and South America had incorporated broad versions of the civil, political, and economic rights of citizens to the point of extravagance (Davis, 1961). Unfortunately, governments in Latin America, throughout the remainder of the nineteenth and the beginning of the twentieth centuries, regularly came to power through violence and were commonly dislodged by revolution. During a 25-year period, from 1930 to 1955, for example, more than 50 violent, mainly military, revolutions took place in the region – to provide an impressive roster of 'military dictatorships' that ruled for variable periods of time (Lieuwen, 1960).

In Africa, military dictatorships became the norm in the decades after the decolonization of European holdings that followed the conclusion of the Second World War. The African military – having a monopoly of coercion at its disposal, and often the only institution having logistical reach over the entire territory – acceded to absolute political power over inhabitants. Control, unconstrained by constitutional limitations, was more frequently than not secured by violence or by the threat of violence.

In fact, the term 'dictatorship' (as distinct from terms like *caudillismo* used in Latin America) came into increased currency in Europe long before its employment elsewhere. At the commencement of the modern period, it came to be used, for example, to designate what was initially understood to be a temporary assumption of full power by what was called the Directorate under Cromwell in England, and in 1793, by the Committee of Public Safety, during the French Revolution.

After the conclusion of the First World War, the term was invoked to distinguish a pattern of rule by 'dictators' such as Benito Mussolini in Italy, Primo de Rivera in Spain, or Mustafa Kemal in Turkey. Actually, what such dictatorships signaled was a development that was far more portentous than simply the identification of the exercise of political power by a single ruler in any particular country. What was emerging was a singular political system, having a relatively specific syndrome of properties that can be legitimately identified as 'modern dictatorship' (Talmon, 1960).

Modern Dictatorship

The dislocations that attended the end of the First World War, gave rise to a wave of revolutionary ferment that involved Eastern and Southern Europe (Lee, 1987). In Russia, revolutionaries first overthrew the Romanov monarchy, and then the provisional democratic government of Alexander Kerensky, in order to impose, in 1917, a 'dictatorship of the proletariat' under the leadership of V.I. Lenin.

According to the tenets of classical Marxism (the Marxism of Karl Marx and Friedrich Engels), the dictatorship of the proletariat was to be a transitional form of minority rule that marked the distance between 'bourgeois democracy' – what Marxists considered to be, in reality, a 'dictatorship of the bourgeoisie' – and communist democracy. Lenin assumed full power over the emerging political system that followed the 'proletarian' revolution (*see* Revolution) by legitimizing it through an appeal to an ideological rationale (Furet, 1999).

At approximately the same time, in 1922, Benito Mussolini led a collection of revolutionaries against the parliamentary and monarchial government of peninsular Italy (De Felice, 1965). Initially what appeared to be a transitional government, calculated to deliver the nation from the crises that followed the First World War, the government of Mussolini quickly took on the features of a modern dictatorship. Through reforms commencing as early as 1925, Mussolini's Fascist regime assumed the properties of permanent minority rule under single-party auspices (De Felice, 1968).

Lenin's proletarian dictatorship and Mussolini's Fascism provide a syndrome of traits that specifically characterize modern dictatorship (Johnson, 1991). In both cases, a charismatic leader exercises almost total control over followers as well as the national community out of which they emerge. Leadership in both cases is epistemarchic in character. That is to say, leadership, in the absence of popular elections, is legitimatized by the leader's putative possession of an ideology that is an inerrant guide to policy, satisfying the needs of the collectivity (respectively the proletariat, or the nation). The inerrant ideology informs the belief system of an organization of believers, usually identified as a 'vanguard' of the revolutionary truth. In the course of time, that vanguard becomes the 'unitary party' of the political system – to the exclusion of alternatives. The inerrancy of the ideology and its attendant policy, in turn, is used to justify control over any and all political dissidence (which, under the circumstances, could only be in error) and any initiatives independent of the vanguard leadership (Manoilescu, 1941).

In general, modern dictatorships maintain a military adjunct to unitary party rule. In the Bolshevik case that adjunct was the Red Army. In the case of the Fascist revolution, that adjunct was the Blackshirt militia. In the case of Adolf Hitler's National Socialism, that adjunct was the "Schutz Staffel" (SS). While military force remains an ultimate recourse of the system, modern dictatorships tend to be populist in disposition. They seek plebiscitary confirmation through controlled elections. Leadership, in modern dictatorships, because it is characteristically 'charismatic,' enjoys life tenure. The Democratic People's Republic of Korea (North Korea), as a case in point, exemplifies such a system. After the Second World War, Castro's Cuba, and Mao's China constituted illustrative instances. The system under the rule of Gamal I Abd' El-Nasser in Egypt, and Ghana under Kwame Nkrumah took on many of the same features. They took on the properties of a modern dictatorship however much their actual practice failed to fully satisfy the criteria for admission into the class.

In most cases, modern dictatorships, whatever their initial character, took on the features of an emphatic nationalism. Having begun as an ideology predicated on class, Bolshevism, as an instantial case, very quickly made recourse to 'patriotism' to sustain popular commitment. All classes and segments of classes in the Soviet Union were expected to be supportive of what were unmistakably national purposes, however 'proletarian' they were supposed to be.

Similarly, given the traits exemplified by such a class of polities, they all failed to allow for what parliamentary and constitutional systems understand to be voluntary association, formal opposition, free elections, the separation of legislative, judicial and executive powers, as well as popular freedom of expression and individual movement. In almost all cases, the charter constitutions of such systems change with some regularity (the constitutions of the People's Republic of China, for example, have changed with every change of leadership) and their provisions are subject to unconstrained interpretation (the provisions of the constitution of Fascist Italy, for example, were subject to the regular reinterpretation of Mussolini and the Grand Council of Fascism).

Modern Dictatorship and Totalitarianism

By the beginning of the 1930s, a subset of modern dictatorships began to evince characteristics that led political scientists to assign them a specific identity: totalitarianisms (*see* Totalitarianism). Possessed of an elaborate security and control infrastructure, supported by a factitious or real consensus, and animated by an irrepressible conviction of their own aggressive moral superiority, such politically repressive systems destroyed millions of innocents, either as a measure of control, or in the pursuit of utopian intention (Horowitz, 1997).

The numbers killed by Stalin, Hitler, Mao, and the Khmer Rouge will probably never be accurately known – but the victims of Marxist–Leninist (*see* Marxism–Leninism: The Ideology of Twentieth-Century Communism) regimes probably exceed 100 million (Courtois et al., 1999). 'Mild' totalitarianisms – like those of Mussolini's Italy, Chiang Kai-shek's

China, or Castro's Cuba – neither particularly homicidal nor genocidal – employ incarceration and exile, together with the characteristic denial of voluntary association and freedom of expression, as means of control.

Whatever the subsequent qualifications on the use of the term 'totalitarianism,' throughout the twentieth century an imprecise subset of modern dictatorships has shared a number of reasonably well-defined traits that qualify them for entry into a specific class of modern political systems (Schapiro, 1972; Soper, 1985; Gleason, 1995). How far into the twenty-first century exemplars of the totalitarian subset of modern dictatorships will persist remains a matter of conjecture.

That such systems can evolve into something like a democratic alternative has been established by the transformation of Chiang Kai-shek's Kuomintang on Taiwan into something very much like a vital democracy. The massive reforms on the mainland of China, that followed the death of Mao Zedong, suggest that such systems have the potential to undergo systemic change. How such change is effected remains uncertain.

Abstract

Originally, dictatorship was an extraordinary magistrature of the ancient Roman Republic. During the nineteenth and, particularly, the twentieth century, the term has been applied to a variety of political system, whose common characteristic was the unlimited concentration of power in the hands of one individual (or of a group of people, a party or institution) holding it for an indeterminate time. According to specific historical circumstances, modern dictatorships have been defined differently, such as Bonapartism, caudillism, authoritarianism, and totalitarianism.

Introduction

Originally, the word dictatorship defined an extraordinary magistrature of the ancient Roman Republic. During the nineteenth and, particularly, the twentieth century, the meaning of the term dictatorship has been substantially modified. In contemporary parlance, the term dictatorship is used to define *any means of governing and any type of political regime based upon the 'unlimited concentration of power' in the hands of one individual (or of a group of people, a party or institution) holding it for an indeterminate time and exercising it without being controlled by either the State's institutions or by its citizens*.

This article will trace the transformation of the concept of dictatorship within the main instances of government to which it has been applied and with regards the principal interpretations of the phenomenon, that is the ensemble of the governmental types defined as dictatorships produced during the twentieth century when the term first became the object of specific historical research and theoretical analysis.

Roman Dictatorship

Origins and Functions

Dictatorship was probably introduced into the constitutional order of the Roman Republic at the beginning of the fifth century BC, soon after the end of the monarchy. Today, the original interpretation of dictatorship as attributed to the survival of the monarchy tradition has been abandoned. A more plausible interpretation is that which sees Roman dictatorship as being derived of an already existing institution in other cities in the province of Latium (Sterling, 1965). The role of dictator could be conferred for the performance of various public duties, the most important being that of the defense of the city and of its rule in situations of serious danger, in the case of external war (*belli gerendi causa*) or internal turmoil (*seditionis sedandae causa*). In these circumstances, full civil and military powers (*imperium maximum*) were conferred upon the dictator for a maximum period of 6 months. The nomination was made by one of the two consuls in office (who could not, however, nominate themselves) upon the request of the senate, which assessed the gravity of the situation. The dictator stepped down at the same time as the consul who had nominated him. All other magistrates were subordinate to the dictator. He himself, however, did not have the power to repeal them nor to pass or repeal laws, modify the constitutional order or nominate his successor. Once the duty for which he had been nominated to fulfill was completed, even before the passing of 6 months, the dictator resigned power to the ordinary magistrates.

The Transformation and End of the Roman Dictator

The dictator remained in force until the third century BC. The last dictator to have maximum civil and military powers was nominated in 216 BC during the second Punic war between Rome and Carthage. When reinstated in the first century BC by L. Cornelius Sulla and later by Julius Caesar during the time of the civil wars that led to the end of the Republic, the dictator's function was radically transformed. The dictatorships of Sulla and Caesar, despite the outward appearance of legality, originated in the force of the army, were conferred for an indeterminate length of time and were used to eliminate political adversaries and to change the order of the Roman State. Roman dictatorship was legally abolished by Mark Anthony in 44 BC, directly following the death of Caesar (*lex Antonia de dictatura tollenda*) and was not reinstated again during the Empire. The term dictator also was not used for many centuries and was not in any case adopted again until the beginning of contemporary times in order to define new exceptional forms of personal power that appeared in the medieval and modern ages in the form of the 'Podestà' of the Italian communes, the Renaissance 'Lords' or Oliver Cromwell's 'Protectorate' (*see* Middle Ages, The; Renaissance; English Revolution, The).

From Roman Dictatorship to Modern Dictatorship

The Model of Roman Dictatorship in the Modern Ages

The term dictatorship, referring exclusively to the Republican magistrature, appeared once again in political writings of modern times such as those by Jean Bodin and Thomas Hobbes who cited it as an example of the fulfillment of the principle of Reason of State and of absolute sovereignty. Niccolò Machiavelli made a decisive contribution to that which we may term the 'apology conception' of dictatorship, understood as exceptional personal government for the purpose of saving the Republic and defending its liberty against internal and external

enemies. The value and the benefit of dictatorship, according to Machiavelli, consist only in the brevity of its duration, otherwise it was harmful to the Republic (*Discourses*, *I*, *10*, *33*, *35*).

This apologetic conception of dictatorship was again proposed in the seventeenth century with the idealization by democratic thinkers of the Enlightenment of 'republican public spirit' (*see* Enlightenment). Jean-Jacques Rousseau argued that in periods of danger the democratic State could nominate a 'supreme chief who silences all the laws', fixing a relatively short period for the fulfillment of his role without the capacity for its being prolonged because only in this way would it be possible to avoid the transformation of dictatorship into tyranny (*Social Contract*, 1762, IV (6): 138).

Dictatorship and Revolutionary Power

The term dictatorship reentered political language at the end of the eighteenth century with the democratic revolutions in America and Europe (*see* American Revolution, The; French Revolution, The). Following the experience of the Public Health Committee, nominated by the Convention (1793–95) both a new conception and practical experience of dictatorship emerged. This was identified by the advent of 'revolutionary power' as a form of absolute government, exceptional and temporary yet personal, which claimed its legitimacy on the basis of the principle of popular sovereignty, the wish to create a new constitutional order and a more just society. After the fall of the Jacobins, François-Noël Babeuf theorized the necessity of dictatorship by a small revolutionary minority in order to seize power by means of insurrection with the end of realizing a 'society of equals'. After the failure of his insurrectionary attempt (1796) the concept of revolutionary dictatorship was taken up by Filippo Buonarroti, a disciple of Babeuf.

Dictatorship in the Nineteenth Century

'Bonapartism' and 'Caesarism' in Europe

In the course of the nineteenth century, the term dictatorship was used in its original meaning by the military leaders of the national revolutions. Simon Bolivar proclaimed himself dictator in 1813; Giuseppe Garibaldi assumed the power of dictator in 1860 during the expedition of the Thousand. The idea of dictatorship was often associated, within nationalism, with the idea of exceptional government for national liberation. Most important, for the history of dictatorship and the transformation of the concept were the new forms of personal regimes founded in Europe by Napoleon Bonaparte (1799–1814) and later by his grandson Louis Napoleon Bonaparte, becoming Napoleon III (1851–70). Their dictatorship originated in a coup d'état. However, they attempted to legitimize their personal power later with a popular plebiscite and with the transformation of the monarchy without formally reneging on the principles of the French Revolution.

These two experiences of government gave rise to the term 'Bonapartism', from then on used to define the new type of dictatorship imposed by a coup d'état but claiming a democratic legitimacy by means of plebiscites. The introduction of the term 'Caesarism' was also used in the definition of this new type of dictatorship, in that Julius Caesar was considered the prototype for the modern dictator, emerging victorious after a period of serious social and civic conflict and imposing his personal power using military strength but also with the support of the masses, presenting himself as the pacifier of the classes, above parties, restorer of stability and of the unity of the State, the incarnation and the interpreter of the national will.

Dictatorship in Latin America

A particular demonstration of a South American version of 'Caesarism' can be found in the presidential dictatorships installed in the majority of the Latin American Republics emerging after independence. These dictators were politicians or military men who elected themselves president and perpetuated their personal power for decades while, nevertheless, paying homage to liberal ideology, allowing for the survival of the constitutional order and, above all, imposing the centralization of state power against the *caudillos*, the local leaders who, in the first years following independence, instituted personal control with the help of the army, the personal fascination with virility and the support of the indigenous and métisse populations. Other president-dictators, followers of positivism, justified their dictatorship with the formula 'Order and Progress' as a necessary means for reinforcing the unity and cohesion of the State, as a pedagogical tool for the education of the people and as a principal factor in the renovation of society and progress. This new version of the apologetic conception of dictatorship remained one of the principal formulae of populist self-legitimation for the dictators that successively dominated South America (*see* Populism).

Apologists for and Critics of Dictatorship

Other versions of the apologetic conception of dictatorship were elaborated in romantic culture, in Catholic reactionary thought, and in positivism: the dictator was variously exalted as the supreme guide of the people, the interpreter of God's will, or the political genius who actuated the laws of history and of progress. Liberal culture, on the other hand, held that the same possibility to confer absolute power upon a single individual was incompatible with the concept of the modern State founded upon the liberty of citizens, on the sharing of power and on the principle of majority rule. The *Dictionnaire Politique* (Duclerc and Pagnerre, 1848) explicitly refuted the treatment of dictatorship as 'an element of modern politics' because 'invoking dictatorship means invoking violence' and annihilating 'the most sacred principle of democracy, that of majority rule' (*see* Liberalism, Anthropology of; Crowds in History).

The Dictatorship of the Proletariat

In socialist thinking, the concept of dictatorship as revolutionary power was developed. Louis-Auguste Blanqui theorized the necessity of the dictatorship of a revolutionary minority for the realization of Communism. This conception was criticized by Karl Marx and Friedrich Engels because their idea of revolutionary dictatorship had to be the *impersonal power* of the working class. The Paris Commune of 1870 represented for Marx, the first concrete attempt at proletarian dictatorship.

In that in a society divided into classes every type of State is no other than the dictatorship of the dominant class, according to the idea sketched out by Marx in the *Critique of the Gotha Programme* (1875), 'proletarian dictatorship' was understood as the organization of the working class at the level of the State following the conquest of power in the transition period from capitalist to Communist society.

The concept of 'proletarian dictatorship' was first elaborated with the conquest of power in Russia in 1917 by the Bolshevik Party led by Lenin. Lenin was a convicted and tenacious advocate of the necessity of dictatorship intended as an unlimited, inflexible, and implacable power in the repression of enemies of the proletariat because, in the absence of this power, the transition from Capitalism to Socialism would be impossible. However, against Marx, Lenin claimed that dictatorship of single individuals, endowed with unlimited power for the realization of the socialist revolution was not in fact incompatible with proletarian dictatorship, exercised by the Bolshevik Party as the vanguard of professional revolutionaries and interpreters of the historical role of the proletariat.

The Leninist conception of dictatorship and its practical activation were criticized by other revolutionary Marxists such as Rosa Luxemburg who claimed that proletarian dictatorship should consist of a means of applying democracy, not of its abolition, and the work of the *class*, and not of a small minority of leaders in the name of the class.

The Twentieth Century: A Century of Dictatorships

The Epidemic of Dictatorship in Europe between the Two World Wars

"In the Victorian Era", wrote Winston Churchill in 1930 in the introduction to one of the first attempts at the historical and theoretical analysis of dictatorship (Forst de Battaglia, 1930), "dictatorship was at once a monstrosity and an anachronism". The triumph of 'parliamentary democracy' in Europe in the aftermath of the Great War was ephemeral. In 1922, the 'crisis of democracy' and the 'crisis of parliamentarism' were already being talked of, while with the affirmation of absolute power by the Bolshevik Party in Russia, a new type of dictatorship as a regime by a single party was being affirmed for the first time. The fascination with the Bolshevik experiment excited masses of European workers and prompted the birth of Communist parties with the aim of violent conquest of power for the establishment of 'proletarian dictatorship'. Nevertheless, no attempt at Communist conquest of power was successful. On the contrary, the fear of Bolshevism generated reaction on the part of the Bourgeoisie and the middle classes in many countries, which led to the creation of authoritarian, nationalistic, and anti-Bolshevik governments. After 1922, almost every year, more or less durable dictatorial nationalist governments emerged in Italy, Spain, Turkey, Poland, Greece, Portugal, Austria, Germany, the Baltic States, and the Balkans.

The Model of Fascist Dictatorship

At the end of 1922, with B. Mussolini's coming to government in Italy (28 October), for the first time a nationalist revolutionary movement organized around a new form of party, the 'party militia', conquered power in a country governed by a liberal democracy with the declared object of destroying it. This gave rise to the establishment of a regime that antifascists were the first to call a 'one-party state', 'totalitarian system', or 'totalitarianism', defining a new type of dictatorship founded upon the predominance of a single party, the centralization of power in the hands of the party leader, the imposition of a singular ideology with the aim of realizing the subordination of society to the State by means of control by the singular party and its organizations (Gentile, 2002).

Until the middle of the 1920s, Fascism, and not Bolshevism, was considered the real threat to parliamentary democracy. Italian fascism effectively became the model for other nationalist movements that proclaimed their dictatorial vocation, openly evoking the ideals of the French Revolution. At the beginning of the 1930s, Europe was invaded by an 'epidemic of dictatorship' (Sforza, 1931). Initially, the dictatorial disease was considered to be exclusive to the backward countries. This interpretation was proved wrong after the rise of National Socialist dictatorship in Germany (*see* National Socialism and Fascism). In the second half of the 1930s, however, the 'seduction of Fascism' seemed to grow (Drabowitch, 1934). During the Second World War, the majority of Southern, Central, and Eastern Europe were governed by dictatorial systems.

Totalitarian Regimes

In the period between the two world wars a new apologetic myth of the dictatorial figure as the 'strong man' who emerges in times of crisis to rescue the State and reestablishes order, discipline, and efficiency was diffused. At the same time, the first attempts at comparative analysis aiming at elaborating a unitary perspective on the phenomenon of dictatorship were began. Already, by the second half of the 1920s, several analogies between the dictatorship of Bolshevism and that of Fascism came to prominence, later compared also to the dictatorship of National Socialism. The classification of these new types of dictatorship under the category of 'totalitarian states' appeared at the end of the 1920s and was already consolidated by the 1930s and 1940s when the first comparative analyses of Fascist, Communist and National Socialist regimes were carried out (see Kohn in Stanton Ford, 1935; Hoover, 1937; Sturzo, 1938 in Sturzo, 1972; Aron 1939 in Aron, 1993; Borkenau, 1939; Cobban, 1939; Proceeding of the American Philosophical Society, 1940; Neumann, 1942). These studies analyzed the new form of dictatorship from the point of view of its most original aspects, neatly distinguishing it from both Roman and nineteenth century dictatorship. These aspects included (1) the peculiarities of the original phenomena of dictatorship, attributed to the legacy of war, the embitterment of class war, the radicalization of politics, the incapacity of the parliamentary system to adapt itself to the tumultuous growth of mass society, and to provide an effective solution to social and economic conflicts; (2) the interest of the masses living through the turmoil of a society undergoing transformation and looking for simple and reassuring solutions by subordinating themselves to the command of a 'strong man' who promised to resolve the

crisis with brutal yet efficient methods; (3) the novelty of contemporary dictatorship as a one-party regime, created by a mass movement that used parliamentary channels, violence, and terror to conquer and maintain power, rendering permanent its own dictatorship and institutionalizing it as a fundamental pillar of a new political system; (4) the personalities of the dictators brought to power by these parties such as Stalin, Mussolini, and Hitler, that is 'new men', emerging from anonymity and rising to power due solely to their political capacity, exalted and revered like demigods by their followers and by the masses; (5) the fanaticism and missionary spirit of the new dictators who endowed their ideology and action with the character of a *secular religion*; (6) the use of methods of technological and organizational modernization for the mobilization of the masses and the development of an intense and constant activity of collective indoctrination; and (7) the ambition of subordinating the collectivity and society to the permanent and capillary control of a *single party* with the aim of creating a new species of human being.

After the Second World War, the end of the Fascist and Nazi regimes, the experience of the Holocaust, the victory and expansion of Stalin's Russia, and the foundations the new Communist regimes in Eastern Europe and in Asia, brought about new interpretations of totalitarianism, highly influenced by the political orientation of Western anticommunism during the Cold War, identifying Nazism and Stalinism as the extreme experiences of the totalitarian dictatorship (Gleason, 1995). To define totalitarianism as a totally new of modern dictatorship, scholars emphasized mass terror as the essence of totalitarianism (Arendt, 1951), the total control over the State and society (Friedrich and Brzezinski, 1956), or the monopoly of political power by a single party (Aron, 1998[1995]).

Totalitarianism: A Controversial Phenomenon

For over 60 years, historians, social scientists, philosophers, theologians have examined the nature of totalitarianism and the effects it has had on the history of humanity (Söllner et al., 1997). However, as often happens when theoretical problems collide with the meaning of human existence, the problems sparked by the debate on totalitarianism are more numerous than the answers given by the experts. There are conflicting opinions even in regards to the definition of totalitarianism, as well as in the application of this definition to political movements and regimes of the 1900s and earlier centuries, starting from the French Revolution. For example, there are those who refuse to identify Communism, Fascism, and National Socialism as totalitarian, and those who support the historical validity of this identification. There are those who believe that the totalitarian theory has a scientific value and those who believe it is only a residue of the anti-Soviet propaganda of the Cold War. Not few misunderstandings on the historical interpretation of phenomena such as Fascism, Communism, and National Socialism have resulted from the issue of totalitarianism. The major objections to the validity of totalitarian theories, stem from the doubt of the legitimacy of adopting a single theoretical model to define such profoundly different historical experiences, favoring similarities, and analogies in action procedures, mentality, behavior, and organization and in political power. Because of this criticism, there was an eclipse of the concept of totalitarianism during the 1970s and 1980s. But, since the end of Communist regimes in Eastern Europe in 1991, there has been a 'revival' of the debate on totalitarianism (Siegel, 1998) as a modern type of dictatorship peculiar of the twentieth century. A new elaboration of the concept has been put forward by scholars who consider that totalitarianism is better understood as a method and a technique of political domination in order to achieve a specific goal, than as a goal per se to be achieved, by stressing the differences as well as the affinities among the totalitarian regimes (Gentile, 2005, 2006).

The Dictatorial Phenomenon after the End of the Second World War

In the aftermath of the Second World War, while parliamentary democracy was being reestablished in Italy and Germany, liberal democracy was definitively consolidated in Western Europe and, after 1945, there were no new dictatorships in this part of the continent. From among the nationalist dictatorships emerging from the interwar period, only the Salazar regime in Portugal and that of Franco in Spain remained standing, both of which returned to democracy after the death of the two dictators in the second half of the 1970s. The only new dictatorship was that of the Colonels' regime in Greece (1967–74).

The phenomenon of dictatorship, nevertheless, enjoyed a new and intensified period of expansion in almost all continents. Only North America and Australia remained uncontaminated by the new dictatorial epidemic. Directly after the end of the Second World War, East Germany, all of Eastern Europe and the Balkans were put under the control of the new Communist dictatorial regimes, the so-called popular democracies, completely subordinated to the political and military hegemony of Stalin's Soviet Union from which only the Communist regimes of Yugoslavia and Albania escaped. From 1949, with the victory of the Communist revolution led by Mao in China, the world's most populous country became governed by a dictatorial regime with its own characteristics, different to the European Communist dictatorships and to those of the Soviet Union. During the 'Cold War', the Communist model, with variations original to each country, inspired the construction of several dictatorial regimes, both civilian and military, in Central America, Asia, and Africa with the help of the two largest Communist countries, the Soviet Union and China, becoming, since the 1950s, rival and antagonistic states both for ideological reasons and for those concerning territorial conflict (*see* Revolutions; Chinese Revolutions: Twentieth Century; Cuban Revolution, The; Vietnamese Revolution, The).

The common characteristics of the Communist dictatorships were (1) the adoption of Marxist–Leninism as their official ideology; (2) the supremacy of the Communist Party as the single and dominant party; (3) the exaltation of the party leader resulting in the institutionalization of the 'cult of personality'; (4) the policed repression of any opposition or dissidence, including the recourse to mass terror; (5) the nationalization and planning of the forces of production and of the economy; (6) the submission to control by the Communist Party of all political and social activities; and

(7) the development of a particular form of 'Communist patriotism', centered upon the myth of the historical mission of the proletariat (Kautsky, 1962).

During the 'Cold War', anti-Communism was the motive and principal ideological justification for the establishment of right-wing, civilian and, more often, military dictatorships sustained by the United States. These dictatorships, especially the military ones (Nordlinger, 1977), when not based exclusively on terrorist repression and the arbitrary use of power in the interests of the dictator, his family or acolytes, attempted to relate policed repression to a demagogic politics of nationalist populism all the while linked to programmes of modernization and development (*see* Modernisation and Modernity in History). In the second half of the twentieth century, dictatorship in the Third World became 'the normal form of government' (Roy, 1977). Almost all the new states emerging in Africa and Asia after the fall of the colonial empires were governed by dictatorial regimes, generally military with a single party created from above, a charismatic leader and a populist ideology of National Socialism with programmes of 'secularization' and 'modernization'. In the second half of the 1970s, in several Islamic countries, religious 'fundamentalism' became the matrix and ideology for new dictatorial governments.

The tendency toward the proliferation of dictatorships came to a halt in the last two decades of the twentieth century, when the number of dictatorships – or governments considered as such –notably diminished (Hamon, 1982). In Latin America, parliamentary democracy was reinstated in the grand majority of states previously governed by dictators. In the late twentieth century, numerous states in Africa were involved in a process of democratization. The fall of the Soviet Union brought about also that of the Communist regimes of Central and Eastern Europe that it sustained (*see* Revolutions of 1989–90 in Eastern and Central Europe). There was a 'third wave' of democratization, as it has been called, to distinguish it from the first 'long' wave of democratization in 1828–1926 and the second, 'short' wave in 1943–62 (Huntington, 1991).

Although it would be too optimistic to declare the definitive death of dictatorship in the contemporary world and the victory of the democracy of human rights (Hermet, 1993), the promotion of human rights has acquired new determination, albeit not always effective, in contesting antidemocratic, repressive, and terrorist governments and in the defeat of the various apologetic conceptions of dictatorship (*see* Human Rights, History of). The breakdown of longstanding dictatorships in some Muslim countries (Tunisia, Egypt, and Libya) during the so-called Arab Spring, in 2011, has paved the way for democracy, and some other autocratic regimes in Muslim, such as Yemen and Syria, are crumbling under the attack of popular insurgence. However, at the present (2012) the countries involved are still in the throes of change. Meanwhile, in the last decade democratic regimes have been under pressure in many parts of the Western world because of longstanding economic crisis, high unemployment rate, growing social inequality, xenophobia, political, and/or religious extremism, corruption in State administration, and the unscrupulous political influence of media tycoons. In most regions the average democracy score for 2011 is lower than in 2010, including the developed countries of North America and Western Europe; there was a decline in the average score for Eastern Europe and small declines for both Asia and Latin America, although these were offset by increase in average scores in the Middle East and North Africa and Sub-Saharan Africa (Economist Intelligence Unit Index of Democracy, 2012). At the beginning of the second decade of the Third millennium, a 'fourth' wave of democratization may be possible, but not for sure.

Contemporary Dictatorship: Problems of Definition and Interpretation

Dictatorship, 'Tyranny', 'Despotism'

In contemporary speech, dictatorship is often associated with tyranny or despotism. Terms such as dictator, tyrant, or despot are often used as synonyms or alternated between. The first students of the phenomenon of dictatorship in the interwar period, while maintaining that the concept of dictatorship is linked to the Roman model of an extraordinary, yet constitutional and temporary, magistrature, preferred to speak of a 'new age of despots', or of a new 'ère des tyrannies' (Halèvy, 1938). In more recent studies also the term 'tyrant' is preferred over that of dictator for defining the numerous ranks of those holding absolute personal power, dominating, in the second half of the century – and still in some cases dominating – in many countries of the so-called Third World (Rubin, 1987; Chirot, 1994). In fact, contemporary dictatorship evokes some of the characteristics of Greek tyranny, but there are also substantial differences. Above all, the origin of contemporary dictatorship is not always illegitimate. For example, Hitler came to power in 1933 through legal channels and many presidents who became dictators in Latin America were legally elected. Furthermore, the majority of modern dictatorships have a very complex structure of organization and exercise of power due to the mass dimension of the societies in which they operate, the methods they adopt and the scopes they propose. All the above makes contemporary dictatorship substantially new and different to tyranny. Therefore, the thesis that holds that the difference between tyranny and contemporary dictatorship as a form of absolute personal power is not substantive but regards solely the form, the technique and method of government should be forcefully rejected.

Dictatorship and the Dictator

Several scholars consider the figure of the 'dictator' an essential and fundamental element in the definition of dictatorship (Cobban, 1939). A large part of the general history of dictatorship consists of collections of biographies that sometimes link, in more or less chronological succession, Greek tyranny and the Roman dictators, Cola of Rienzi and Girolamo Savonarola, Cromwell and Robespierre, the two Napoleons, the 'caudillos' and the authoritarian and totalitarian dictators of the twentieth century (Hallgarten, 1957). Some students maintain that governments in which unlimited power is not concentrated in one individual cannot be defined as dictatorships in the proper sense of the term. The identification of dictatorship with the figure of the dictator is certainly justified in the majority of the cases in history. In almost all

contemporary dictatorships, the dominant personality of one man emerged at the outset or was subsequently imposed, often surrounded by a 'charismatic' and 'sacred' fascination with the cult of the personality (Schweitzer, 1984). At the same time, dictatorial governments exist without the figure of the dictator. For example, the Soviet Union following Stalin's death and the dictatorial regimes governed by military juntas. Moreover, not even in totalitarian regimes that appear to be internally controlled by the personal power of a dominant and charismatic figure, can the nature and character of the dictatorship as a system of power founded upon the single party be identified in the personage of the dictator (Schapiro and Lewis, 1970; Tucker, 1972).

Definitions and Typologies

Contemporary dictatorships are extremely heterogeneous: civilian or military, personal or collective, conservative or revolutionary, traditionalist or modernizing, bureaucratic or charismatic, authoritarian or totalitarian. Moreover, not only do contemporary dictatorships have nothing in common with their ancient predecessor, apart from the concentration of power, they also differ extensively between them according to the geographical, historical, and cultural contexts in which they emerge and due to the economic, political, and social situations that give rise to them. Furthermore, they differ as regards the social origins of their protagonists as well as the latter's political formation, the modes in which power and methods of action are organized, the ideologies they profess, and the scopes they propose. Finally, differences exist relative to the historical development of their emergence, the results they have achieved, and the legacies they have left.

Given the variety and complexity of the phenomenon of dictatorship in the twentieth century, it is very difficult to elaborate a general, unitary theory of dictatorship. Several fundamental problems therefore remain unsolved, particularly those that concern the specific nature of contemporary dictatorship with respect to other forms of absolute personal power. There are various definitions and typologies for classifying the numerous forms of unlimited concentration of power appearing during the course of the twentieth century, commonly adopting the term dictatorship albeit with a meaning varying widely from the original (see especially Schmitt, 1928; Friedrich and Brzezinski, 1956; Neumann, 1957). There are some scholars, however, who prefer to use the term dictatorship in reference only to its original meaning, finding the term 'antidemocratic regime' more appropriate for defining the modern forms of unlimited concentration of power, be they authoritarian or totalitarian (Linz, 2000). The identification of contemporary dictatorship with antidemocratic regimes is, however, only one aspect of a much more ambiguous relationship between contemporary dictatorship and democracy, understood as the affirmation of the principle of popular sovereignty and mass participation in political life. Contemporary dictatorship searches for its own formula of legitimation within the principle of popular or national sovereignty, and this is particularly noticeable in certain states in Africa, in the Middle East, and across Asia. The 'third' wave of democratization has not resulted everywhere in stable democratic regimes, but in pseudo-democratic new autocracies, even if they claim their democratic legitimacy because of plebiscitary support in national elections. A variety of new concept has been elaborated such as 'semidictatorship', 'semidemocracies', 'hybrid regimes', to define the regimes that combine democratic and authoritarian features (Ottaway, 2003).

Conclusion: General Characteristics of Contemporary Dictatorship

The diversity in the experiences of power defined as dictatorship in the contemporary world, the variety of definitions and typologies and the problems remaining controversial regarding the nature of dictatorship do not, nonetheless, impede us from being able to identify at least some common characteristics enabling the definition of the specificity of the phenomenon of dictatorship in the modern era in their formative or stabilizing phases (Ezrow and Frantz, 2011).

According to the definition furnished at the beginning of this article, all types of government and regime in which a single person, a group of people, a party, a military or religious institution (1) conquers the monopoly over political power, by legal or illegal means, and maintains it for an indeterminate length of time; (2) suppresses, reduces, or impedes citizens' enjoyment of their civil or political rights; (3) forbids or represses the activities of dissidents or of the opposition with the use of force and with recourse to terrorist means; and (4) excludes *de facto* the possibility for the legal and pacific repeal of the rulers by the ruled even while allowing for electoral consultations and plebiscites to take place may be included under the category of contemporary dictatorship. Contemporary dictatorship is, thus, the antithesis of democracy understood as a representative political system based upon the division and balance of power, a respect for the personal and public rights of citizens, on freedom of speech and of association, on the periodic election of the government by the electorate, by means of a free and peaceful political contest and according to legal procedures guaranteed by the constitution.

Differential Aging

Abstract

Differential aging refers to the principle that the rate of functional changes in various life domains shows inter- and intra-individual variability. The study of differential aging may be traced to large-scale investigations identifying different patterns of aging. Current models of successful aging provide insight into the differential aging process as experienced by individuals showing optimal age-related changes. A biopsychosocial model provides a useful framework for organizing these models. As translated into successful brain aging, such approaches identify those individuals who maintain superior levels of neurological integrity which, in turn, translates into superior cognitive performance. Personality, health, and sociocultural factors further interact with age-related changes in the brain and cognitive functioning. Future research will continue to expand the knowledge base in this important, and growing, field within life span psychology.

Differential aging refers to the principle that the rate of functional changes in various life domains shows inter- and intra-individual variability. Interindividual variability is shown by the fact that there are differences across individuals in the rate at which changes occur over time. Intraindividual variability is demonstrated by the finding of differences in the rates of change over time in functions within the same individual. The principle of differential aging stands in sharp contrast to the previously held views in developmental psychology that aging is a uniform process of decline, also known as dedifferentiation. Although it is true that death is the inevitable outcome of the aging process, this fact does not rule out the possibility that growth can occur in psychological functions even at the end of life. Plasticity is another component of differential aging, meaning that the potential exists throughout later adulthood for growth and adaptation.

Several distinctions within the aging population already exist, which make it clear that individuals show important differences in their patterns of change over time. One is the division of the 65 and older population into subdivisions of young–old (65–74), old–old (75–84), and oldest–old (85 and older). The second set of divisions of older adults takes patterns of change over time into account. Individuals may show primary (normal) aging and secondary (infirmed) aging. At the very end of life, as their health rapidly decreases, tertiary aging becomes the norm as multiple functions simultaneously decline.

According to the principle of differential aging, the appropriate study of development in later life is on providing an understanding of why people vary in the ways they age. In the area of brain functioning, where much of the differential aging research is now taking place, neuroimaging technology is making it possible to correlate variations in abilities between and within older adults with variations in the rate of brain aging. Statistical methods for modeling individual change over time are becoming the standard for analytic methods in longitudinal and sequential research. The goals of much of this research are not only to reflect more accurately the nature of the aging process, but also to provide the basis for effective interventions to improve the daily lives of older adults.

The Origins of the Principle of Differential Aging

The term differential aging was introduced in the literature by Hans Thomae, one of the original collaborators in Bonn Gerontologic Longitudinal Study (BOLSA). BOLSA was started in 1965 with two cohorts born in 1890–95 and 1900–05, following survivors for 15 and 19 years, respectively. BOLSA data linked patterns of aging defined by health, cognitive and social abilities, coping, and personality with social structural variables including socioeconomic status, gender, and other social variables. Findings from BOLSA, which included predicting longevity from psychosocial variables, reinforced the view that the study of aging requires a multidimensional approach.

The concept of differential aging became a central component of the Berlin Aging Study (BASE), a comprehensive investigation begun in the late 1980s of over 500 adults between 70 and 100 years of age living in Berlin, Germany. This study continued the mission of BOLSA to understand patterns of aging and provide insight into why some people age successfully and some do not. BASE also recognized that successful agers do not show uniformly positive trajectories of change. Thus, the goal of this literature was to understand how individuals balance their gains and losses with age in such a way as to maintain their physical and mental health.

The selective optimization with compensation (SOC) model was developed in the context of BASE as a way to understand the factors that influence successful aging. Selection occurs when individuals actively or passively reduce the number of goals and domains in order to free up energy for investing in new or more important goals. Individuals engage in compensation when they search for and use alternate means to reach their goals once they can no longer use their previous means. BASE showed that older individuals most likely to achieve successful aging by the criteria of maintaining an active lifestyle across 21 indices of everyday functioning were those rich in sensorimotor–cognitive and personality–social resources (Baltes and Lang, 1997).

A follow-up to the original BASE tracked the trajectories of groups defined on the basis of scores on constructs measuring cognition, personality, self-rated functioning, and

social integration (Gerstorf et al., 2006). These scores, obtained over three measurement occasions, were used to define three clusters among a subset of the original sample: an overall positive profile; an overall average profile; and a high cognition, low self, and social profile. Impressively, over the 6-year period, the majority of individuals remained in their relative subgroups. Regardless of which group they were in, though, individuals who changed group membership showed the highest rates of mortality. In a subsequent follow-up conducted 7 years later, however, 'dedifferentiation' occurred. There was less evidence in favor of correlates of differential change as all groups showed a cascadelike descent prior to mortality. Nevertheless, given that individuals vary in dying trajectories, some differentiation may still exist even toward the very end of life.

Differential Aging: Perspectives from Successful Aging

The initial BASE findings make clear the fact that aging progresses at differential rates in part, at least, due to the differential availability of resources as well as the individual's ability to be able to maximize his or her use of those resources. In addition, as was clear in BASE, the concept of differential aging assumes an integrated biopsychosocial perspective that brings together biological, psychological, and sociocultural factors as they impinge upon, and change, across the life span.

The most well-known approach to successful aging was, for many years, the Rowe and Kahn model (1998). This model identifies the three components of successful aging as lack of disease and disability, high cognitive and physical functioning, and engagement with life. The Rowe and Kahn model would imply that adults who age successfully do not have physical or cognitive limitations and are vitally involved with their social context.

Critics of the Rowe and Kahn model argue that it is overly focused being free from infirmities that inevitably accompany aging, even in the healthiest older adults. Moreover, as BASE showed, older adults have differential access to the social resources that can support their ability to age successfully. The model does not account for these contextual factors. Older adults with social support, particularly support from family, are most likely to have high ratings of successful aging. Such support would make it more likely that the older adult would meet the criteria of remaining engaged with life (Reichstadt et al., 2007).

Perhaps for these reasons, researchers employing the Rowe and Kahn criteria find that only a small minority of older adults age successfully. In comparison, the large majority of older adults in the U.S. report high feelings of subjective well-being. The National Health Interview Survey, which tracks the incidence of serious mental illness, reports year after year that adults of 65 years of age and older report lower rates of serious mental illness within the past year than do younger age groups of adults (Substance Abuse and Mental Health Services Administration, 2012).

Thus, the Rowe and Kahn criteria may be too strict in requiring lack of disability to be a criterion of successful aging. In the Health and Retirement Study (HRS), a longitudinal investigation of adults of 51 years of age and older, successful aging was defined as involving no major disease, no limitation in activity of daily living, ability to perform a variety of physical tasks (such as walking one block), high levels of cognitive function, and active engagement in work, volunteer activity, or interactions with family, neighbors, and friends (McLaughlin et al., 2010). The HRS measures were assessed over four time intervals from 1998 to 2004.

The percentage of the HRS sample who met all four criteria for successful aging decreased over the 6 years of the study from about 12 to 11%. Roughly half of the sample met the criteria for successful aging across the entire 6-year period in terms of active engagement, high cognitive functioning, and high physical functioning. Approximately 80% met the criterion of no disability, even by the end of the period. However, only 43% reported having no disease at the beginning of the study, and even fewer (37%) did by the point of the final data collection.

The failure of Rowe and Kahn model to give sufficient attention to social context is supported by the fact that in the HRS, successful agers were more heavily represented among Whites and among those with a college education or higher (McLaughlin et al., 2010). Results from the Survey of Health, Ageing and Retirement in Europe (SHARE) on 22 464 men and women in 13 European countries averaging 63 years of age further reinforces this point (Brandt et al., 2012). In SHARE, early childhood conditions including parental social class and income predicted late life successful aging as measured by the Rowe and Kahn criteria. These findings reinforce the point that differential aging reflects not just current, but also lifelong influences of multiple factors, including favorable or unfavorable childhood conditions. Thus, although Rowe and Kahn count social engagement as a criterion for successful aging, social context conceived more generally needs to be given greater attention.

Further evidence for the role of social context comes from a study of life satisfaction across the adult years in two studies of large national samples showing different age-related patterns. Baird et al. (2010) used self-rated happiness data from the German Socio-Economic Panel Study, begun in 1984 with a full sample of over 40 000 participants who were followed over time, along with new samples added at each testing occasion. The final sample available for analysis consisted of nearly 21 000 adults who had participated an average of eight times. After controlling for cohort, time of measurement, and number of testing occasions, the picture that emerged was of near stability in life satisfaction until the very oldest ages, beginning at the age of 70. However, when they conducted similar analyses on the British Household Panel Study, a different pattern emerged. Life satisfaction among this sample decreased early in adulthood, increased from mid to late adulthood, and then declined at the very end of life. Thus, although the end points were similar in that a decline in life satisfaction emerged in both samples, there were differing trajectories for adults in the two countries.

Social class may play a role in affecting successful aging through its relationship with physical health. In analyses of 12-year longitudinal data from the German Aging Survey (Schöllgen et al., 2012), scores on a measure of negative emotions predicted change in physical health in individuals with lower levels of education. In contrast, physical health was related to change in positive emotions over time independently of educational level.

Taking social context into account is the model of active aging put forth by the World Health Organization (WHO) (2002). The WHO model specifies roles for social, health care, and economic determinants as well as pointing to the importance of the physical environment, thus incorporating into its definition recognition of the fact that older adults may be operating under a number of constraints outside of their own personal control. Noteworthy is the fact that WHO places greater emphasis on the individual's ability to get around in the environment, rather than on whether or not the individual needs physical accommodations due to disability, thereby further broadening the definition of successful aging.

However, neither the Rowe and Kahn and WHO definitions take into account psychological factors such as personality and identity. Vahia et al. (2012), using data from the San Diego site of the Women's Health Initiative, developed a dimensional model of successful aging that went beyond cognition and physical functioning to include psychological resilience, optimism, and self-efficacy. Similarly, Ouwehand et al. (2007) proposed that greater attention is to be paid by successful aging models to proactive methods taken by older adults to adapt to life stresses. Critiquing the SOC model, they note that older adults can in fact achieve their desired goals, rather than having to pare them down, through proactive coping in which they prepare for potential stressors, anticipating events that they believe represent a threat to their well-being and then engaging in mental preparation to reduce the impact of the stress when it occurs. When the stressful event does occur, it will drain less of their coping resources.

Thus, both social context and self-perceptions seem to be important in assessing the factors that influence resilience in the form of successful aging in later life. Models of differential aging must therefore go beyond objective, within-person focused criteria and incorporate the strategies that older adults use to navigate the biopsychosocial effects of aging that might otherwise thwart their abilities to achieve high levels of subjective well-being.

Differential Brain Aging and Successful Cognitive Aging

The concept of successful aging is becoming a central organizing theme in research on brain and cognitive aging. It has long been known that individuals differ in the rate of central nervous system aging which, in turn, is reflected at least in part in differences across and within older adults in their levels of performance on cognitive tasks. Researchers are now attempting to identify the factors that contribute to successful brain aging and, by extension, successful cognitive agers.

An overarching framework in differential brain and successful cognitive aging is provided by scaffolding theory (Park and Bischof, 2013), which provides an elaborate model indicating the interaction among aging, compensatory activities, and the possibility for neural growth in later adulthood. According to this model, normal aging brings with it amyloid accumulation, shrinkage, changes in white matter such as development of hyperintensities, cortical thinning, and depletion of dopamine, which can affect prefrontal function. These structural challenges combine with age-related deterioration of functioning such as losses in the visual area, decreased ability to recruit the medial temporal lobe, involved in memory, and increased default activity, which leads to an increase in interference from background thoughts during effortful cognitive activity.

Counteracting these deleterious changes is scaffolding, a process that allows older adults both to compensate for and even enhance cognitive functioning. Compensatory scaffolding includes recruiting the anterior or frontal regions of the brain to increase its activity to make up for decreased activation of the posterior regions ('PASA'). New neurons can even be generated to replace those lost through cell death ('neurogenesis'). Older adults also seem to show more distributed processing of information and greater bilaterality in which the opposite hemisphere takes over when the original hemisphere suffers losses (Hemispheric asymmetry reduction in older adults, 'HAROLD') (Cabeza, 2002). Older adults may also use the process of scaffolding enhancement in which mental and physical activity as well as engagement contribute to maintain or build upon the individual's existing cognitive resources. For example, older adults with higher levels of physical fitness have enhanced hippocampal volume and spatial memory (Erickson et al., 2009). All of these factors combine to produce the older individual's level of cognitive function. With so many variables at play, it is clear that a number of alternative pathways are possible in the process of brain, and hence cognitive, development in later life.

The search for successful cognitive agers includes several lines of investigation in which objective criteria are used to define what are now being called 'SuperAgers'. One way to identify such individuals is to use statistical criteria defining these high-functioning older adults as being above the average for an individual's age group (Fiocco and Yaffe, 2010). Another approach is to define successful cognitive agers in an absolute sense. Harrison et al. (2012) identified a group of 'SuperAgers', who were individuals of 80 years of age and older with memory performance equivalent to that of middle-aged adults.

The SuperAgers identified by Harrison et al. (2012) were found, on MRIs, to have thicker cerebral cortex volume. Their memory performance, in turn, was correlated positively with the cortical thickness. The SuperAgers also showed greater volume of the cingulate cortex, an area that may be involved in preventing episodic memory loss.

However, the sheer size of a brain region may not be as important as the way that brain region is organized or functions. In a review of 80 studies comparing brain function and cognitive performance in older adults, Eyler et al. (2011) looked for relationships between MRI and PET scan activity in the cortical lobes and subcortical areas involved in movement, sensory processing, and the insula, located deep within the cortex. In 61% of the studies reviewed there was either a mixed relationship, a negative relationship, or no relationship at all between brain aging and cognitive aging. More of the positive associations between brain activity and cognitive performance showed up for the frontal cortex (35%). In the medial temporal lobe, which includes the hippocampus, there were far fewer significant relationships (20%). Consistent with the HAROLD and PASA compensation models, it is possible that the successful brain agers are most likely to show greater abilities to take advantage of brain compensatory scaffolding.

Differential aging also occurs within regions of the brain with association areas, neostriatum and cerebellum more

affected by aging than the sensory cortices and the subcortical area of the pons. Subcortical white matter and hippocampus also show losses in later life, rates of shrinkage that may be accelerated in individuals suffering from hypertension (Raz and Rodrigue, 2006). Differential changes also occur in myelinization versus coherence of fiber organization within the white matter of the brain (Bennett et al., 2010). Variations according to gender are evident in many areas of health and physical functioning, and there is evidence that such differential aging in the brain occurs in the putamen, a structure in the basal ganglia involved in motor function (Nunnemann et al., 2009).

A number of investigations of sensory, perceptual, and cognitive functions and their connection to brain activity, similarly, point to the importance of assessing not only mean differences between age groups but also the existence of intra-individual and interindividual variability. Such functions include, for example, executive functioning (Goh et al., 2012), involved in planning and organizing cognitive operations. Aging has differential effects on regions of the brain, across and within individuals, as well as differential relationships to behavioral performance indicators.

These findings on brain aging are consistent with the work of Schaie and colleagues in the continued investigations based on the Seattle Longitudinal Study (SLS), a program of research using a sequential research design to identify age, cohort, and time of measurement influences on intellectual performance. Overall, the findings reveal a picture of intelligence in later adulthood as one of stabilities until the 50s or 60s, followed by decline through the oldest ages tested. However, there are important qualifications on this conclusion. First, although some individuals may show declines in intelligence by the mid-50s, significant losses do not occur overall until the decade of the 70s. More to the point, changes in functioning do not occur across all abilities, even into the decade of the 80s. There are distinctly different patterns of age changes across the primary abilities. Vocabulary, a measure of crystallized intelligence, showed the least amount of change, holding up fairly steadily until 74 years of age. The largest drop in scores occurred on quantitative knowledge. Moreover, health status also contributes to individual differences in intelligence. Arthritis, cancer, and osteoporosis are health conditions associated with intelligence test scores (Schaie, 1996). These effects are not limited to Western countries; similar findings were reported among a study of more than 3200 Chinese of 60 years of age and older, even after controlling for age, smoking, hypertension, and diabetes (Liu et al., 2009).

Supporting these findings of differential aging patterns are analyses from the University of Manchester Longitudinal Study, conducted over a 20-year period on over 6000 middle-aged and older adults (Ghisletta et al., 2012). In this study, tests measuring fluid intelligence declined at a faster rate than did those of crystallized. However, confirming findings from the SLS, there were large individual differences, particularly during the midlife years. There is also increasing evidence showing a relationship between measures of brain activation and intelligence test performance with fluid intelligence fluctuating to a larger degree among older adults with higher levels of abilities (Ram et al., 2005). Perhaps the individuals at the lower end of the spectrum are more vulnerable to the physiological changes that, in turn, can further erode their fluid abilities in a cascading effect.

Individual differences in intelligence test scores are related to social and cultural factors as well. People with higher levels of education receive higher scores on fluid intelligence measures and, in fact, when controlling for education, even cross-sectional differences in middle adulthood disappear (Ronnlund and Nilsson, 2006). These findings support the WHO model of active aging and its inclusion of social and cultural factors as playing a role in differential aging.

Application to Cognitive Functioning

Replacing the focus on mean differences between younger and older adults on tests of cognitive functioning is increasing emphasis on variations within older groups of adults studied cross-sectionally and variations over time in longitudinal studies of cognition and aging. Why older adults show these variations also is becoming the basis for new theories of aging and cognition. For example, Salthouse in refining his general slowing hypothesis, incorporates more complex models of the effects of aging on speeded performance and verbal intelligence (Bowles and Salthouse, 2008).

Differential aging also becomes relevant to understanding association memory and age. Visual and spatial working memory also appear to show differential age patterns (Oosterman et al., 2011) as does learning of emotional and nonemotional stimuli (Monti et al., 2010), voluntary and involuntary autobiographical memory (Schlagman et al., 2009), and prospective and retrospective memory (Kvavilashvili et al., 2009). Older individuals also differ in their use of strategies in working memory tasks (Bailey et al., 2009). Across the life span, top-down and binding processes in memory show differential patterns of change, with top-down processes showing a greater contribution to working memory in older adults, whereas processes that bind working memories are more subject to age-related declines (Sander et al., 2012).

These are just a few examples of the paradigm shift taking place in research on aging and cognition. Instead of recording differences between groups of younger and older adults, researchers are now examining variation and possible causes for variation within older samples.

Application to Personality and Social Functioning

As noted above, identity and personality must be taken into account in any model of differential aging. Not only do individuals possess differing degrees of resilience and sense of control, but also their life experiences contribute to their overall sense of self, experiences best understood from a bio-psychosocial perspective.

First, identity influences and is influenced by the challenges associated with negotiating the aging process (Whitbourne et al., 2002). Individuals show differing degrees of incorporating age-related physical and cognitive changes into their identities through their use of identity processes. They may use identity assimilation, in which they attempt to minimize or even deny the extent to which they are undergoing these changes. In part, identity assimilation may be a defensive way to ward off the negative stereotypes of aging present in Western society (Sneed and Whitbourne, 2003). Conversely, through identity accommodation, older adults incorporate these

changes into their identities, potentially to the point of believing that they cannot ever live the life to which they have become accustomed. The process of identity accommodation may itself create further problems, such as when older adults begin to believe that they do not have control over their own aging (Jones et al., 2009). Ideally, however, older adults achieve a sense of balance between these processes in which they are able to acknowledge the reality of the fact that they are getting older without becoming despondent. Cross-national studies show differences in the extent to which older adults use these processes reflecting, in part, the social and economic environment in which they are aging (Westerhof et al., 2012). Moreover, they may change in their relative use of these processes in a dynamic way as they confront each new age-related change in functioning (Whitbourne and Collins, 1998).

Looking next at personality, studies of aging based on the scales of the Five Factor Model show a high degree of consistency over time throughout adulthood, with greater consistency among increasingly older groups of adults. This means that people maintain their relative positions along the traits in comparison to their age peers. However, the consistency between scores obtained at different measurement points becomes smaller as the time interval between them becomes longer. Although people may maintain their relative positions along each of the traits, their mean scores may undergo change across adulthood. Roberts et al. (2006), based on a meta-analysis of 92 longitudinal studies, concluded that individuals increase in social dominance, conscientiousness, emotional stability, social vitality, and openness to experience through 40 years of age; after that point, social vitality and openness decreased after this point, and agreeableness increased.

Personality may also play a role in the maintenance or decline of cognitive abilities. Individuals who feel confident in their abilities are liberal and autonomous in attitudes, and have an open-minded approach to new experiences, thoughts, and feelings also have higher intelligence test scores in later adulthood (Schaie et al., 2004). In contrast, older adults who are higher on trait anxiety perform more poorly on a variety of fluid and crystallized tasks (Wetherell et al., 2002).

People higher in openness to experience when young, may benefit from a lifetime of curiosity and willingness to entertain new ideas. In the Aberdeen Scotland Birth Cohort of 1936, longitudinal study begun when participants were children, those high in this trait had higher scores on measures of reading ability in the decade of the 60s (Hogan et al., 2012). Similarly, in an Australian study on adults of 74–90 years of age, participants higher on one aspect of openness to experience (enjoyment of fantasy) had superior intelligence and everyday functioning test scores (Gregory et al., 2010). However, in both of these studies, personality alone did not serve to predict intellectual functioning. In the Aberdeen study, childhood intelligence was a stronger predictor of cognitive ability in later adulthood than personality openness. The Australian study showed that fluid intelligence interacted with personality openness in influencing cognitive abilities. It is possible that people with higher intelligence are higher in personality openness, which allows them to achieve superior cognitive performance.

These studies raise the question of directionality in the cognition–personality relationship. The intellectually more able may seek out more stimulating environments, or being in an environment rich in cognitive stimulation may lead to greater preservation of cognitive abilities. Perhaps the successful cognitive agers purposefully search for ways to maximize their abilities by seeking complexity in their daily activities. In research from the Zurich Longitudinal Study on Cognitive Aging, a factor formed by items assessing reading, problem solving, abstract thinking, and intellectual curiosity in everyday life predicted higher crystallized intelligence scores (Dellenbach and Zimprich, 2008).

Suggestions for Future Research

Despite the existence of the principle of differential aging, many researchers within psychological gerontology and life span psychology continue to focus their efforts on the search for consistent patterns of age differences that characterize older adults as a homogenous group. However, as indicated by the studies reviewed here, the principle of differential aging is starting to take hold as a framework for understanding inter- and intraindividual variation in a range of abilities. Moreover, new models that take into account the broad range of factors influencing well-being in older adults, such as WHO's focus on active aging, will broaden and deepen scientific understanding of the contribution of biopsychosocial processes or successful aging.

Summary

The principle of differential aging originated from broadscale investigations of intra- and interindividual variations in patterns of aging. Operationalizing differential aging as successful aging links this principle to efforts to identify contributions to successful aging which, in turn, is increasingly being understood as a biopsychosocial process.

Within the past 10 years, studies in the fields of aging within neuroscience, cognition, and personality are identifying patterns of differential changes across the adult age span as well as differential changes within individuals in particular types of abilities. Moreover, these studies either directly provide linkages among biological, psychological, and sociocultural factors or allow for interpretations that bring multiple disciplines into the equation.

It is clear that differential aging will continue to serve as an organizing principle and provide a rich conceptual model to inform future research and theory in gerontology and life span development.

Abstract

Differential diagnosis may be defined as the application of a systematic diagnostic method to distinguish one disease or condition from multiple candidate conditions, presenting with similar sign and symptoms. However, in psychiatry, differential diagnosis is more complex than in other branches of medicine, given that the etiology of mental and behavioral disorders is still largely unknown and no biological tests or instrumental diagnostic procure is available, yet. Along the past four decades, the introduction of operational criteria has increased the reliability of psychiatric diagnoses, but it has also let arise many clinical problems (ranging from the inflation of psychiatric comorbidity to the loose boundaries between different diagnostic categories, from the gradual abandoning of the concept of disorders' spectrum to the issue of diagnostic hierarchy).

The etymology of word 'diagnosis' (which derives from the two Greek words *dia*, meaning 'through,' and *gnosis*, meaning 'knowledge') drives any clinician to the idea that, prior to treat any human suffering, a journey through the patient's sign and symptoms is essential. In some cases, the clinical presentation is often seen and easily recognized; in very few cases, one symptom or sign may be specific for a single pathological condition (i.e., a 'pathognomonic' signs or symptoms); in the former cases, the diagnosis is relatively a simple procedure. However, most commonly, similar clinical presentations may be caused by different etiologies and thus respond differently to different treatments; these cases have to be systematically evaluated to identify a single pathological entity, among multiple alternatives. Differential diagnosis may be defined as the application of a systematic diagnostic method to distinguish on disease or condition from multiple candidate conditions, presenting with similar sign and symptoms. Actually, as simple as they may seem, the great majority of diagnoses are the result of a differential diagnostic process.

In epistemic terms, a differential diagnosis procedure is essentially a specific application of the hypothetic-deductive method; in practical terms, it is a process of elimination which, based on the information obtained, allows the investigator to reduce the probability of the candidate conditions to negligible levels, except for the final diagnosis.

Similarly, in medicine, the concept of differential diagnosis refers to a systematic method of investigation and stays as a core medical skill, because it represents the preliminary foreword to any focused, specific, and effective treatment. For example, a patient complaining of recurrent upper abdominal pain may probably suffer from a hiatus hernia (an anatomical defect allowing regurgitation of stomach contents into the gullet), but the symptoms may be cardiac in origin (angina), or the result of a gastric or duodenal ulcer, or even of a gastric cancer, and thus it is important to exclude these possible alternative diagnoses before treatment starts.

In medicine, differential diagnosis follows four basic steps: (1) gathering information about patient's history, signs, and symptoms; (2) listing all possible candidate conditions for the observed signs and symptoms; (3) prioritizing the conditions (usually, based both on dangerousness of the condition and on its frequency of presentation, so that the most urgent and frequent diagnoses stay at the top of the list); (4) ruling out the false clinical hypotheses.

In principle, differential diagnosis in psychiatry is no different from that in any other branch of medicine. In practice, however, there are a number of important differences, because of our limited understanding of the causes (i.e., the 'etiology') of most mental disorders. A medical diagnosis is often achieved by means of biological tests or instrumental investigations: the access to *in vivo* information allows the clinician to perform the fourth step of the differential diagnostic process with greater confidence and to rule out many conditions easily. On the contrary, a psychiatric diagnosis is usually determined by the patient's symptoms and behavior, and by their temporal evolution. Indeed, only few psychiatric disorders (mainly, dementias) are defined by their neuropathology, but as this can only be determined after death and thus even such diagnoses have to be based on the presenting clinical syndromes. Until the understanding of the etiology of psychiatric disorders increases, differential diagnosis in psychiatry will imply significant differences and peculiarities with respect to that of most branches of medicine.

The Logic of Differential Diagnosis in Psychiatry

In the seventeenth century, all medical diseases were defined just by their clinical syndromes (i.e., by the symptoms the patient complained of, the clinical signs elicited by the physician on examination, and the evolution over time of these symptoms and signs). Over the last 400 years, however, increasing understanding of the etiology of most of these diseases and the availability of newer technologies allowing to explore *in vivo* functioning of the human body has resulted in their being redefined at some more fundamental level. Smallpox is now defined, not by its characteristic rash, high fever, and mortality, but by the presence of the variola virus; cancer of the stomach is defined, not by the patient's rapidly worsening indigestion and palpable abdominal mass, but by the histopathology (i.e., detailed microscopical structure) of the tumor; thyrotoxicosis is defined, not by the patient's goiter, weight loss, and bulging eyes, but by a raised blood level of the thyroid hormone thyroxin, and so on. As a result, the diagnosis

of most diseases depends on the results of laboratory investigations. Although the physician usually has a shrewd idea which diagnoses are likely after examining the patient, the provisional clinical diagnosis needs to be confirmed by the laboratory: a diagnosis of smallpox is only provisional, until the variola virus has been identified; a diagnosis of cancer of the stomach has to be confirmed by histological examination of the tumor; and, a diagnosis of thyrotoxicosis has to be confirmed by demonstrating a raised blood level of thyroxin.

The difference between psychiatry and the rest of medicine is not absolute, however. Several neurological disorders, such as migraine and torticollis, are still defined by their syndromes, and so too are some skin disorders, such as pityriasis rosea. Conversely, some neuropsychiatric disorders, such as Alzheimer's disease, vascular dementia, or Creutzfeldt-Jakob disease, are defined by their neuropathology. Their defining characteristics are comparable, in other words, with those of cancer of the stomach. But even here there is an important practical difference. The histopathology of a gastric tumor can be determined by taking a biopsy through a gastroscope, or at operation, whereas the histopathology of the brain can normally only be determined *post mortem*, and this means that the diagnosis on which treatment is founded still has to be based on the clinical syndrome.

Yet at present, there are only a few neuropsychiatric disorders that are defined by the presence of a fundamental abnormality, which can be identified or excluded during life. Down's and Klinefelter's syndromes are both defined by the presence of chromosomal abnormalities: the former by an additional chromosome 21 and the latter by an additional X chromosome. Huntington's chorea and the Fragile X syndrome are both defined by abnormal genes at specific sites, and phenylketonuria (another important cause of mental retardation) is defined by a specific biochemical abnormality. However, besides the above mentioned chromosomal abnormalities, the understanding of the etiology of most psychiatric disorders is still rather rudimentary and they still have to be defined by their clinical syndromes.

In psychiatry, diagnosis, and hence differential diagnosis, is determined by the patient's symptoms (abnormal or distressing subjective experiences reported by the patient) and behavior (observed or reported by others), and the temporal evolution of these abnormalities. Apart from age and sex, information of other kinds, particularly from laboratory and radiological investigations, are rarely relevant; and even if they are relevant, they are not decisive. Eventually, of course, as understanding of their causation develops, most psychiatric disorders will either be redefined in terms of an underlying abnormality of some kind, or be replaced by new diagnostic concepts defined in this way. At that stage differential diagnosis in psychiatry will probably be no different from that in any other branch of medicine. Until then, however, problems of differential diagnosis have to be handled differently.

History of Differential Diagnosis in Psychiatry

According to the Merriam-Webster medical dictionary, the term 'differential diagnosis' has been introduced around 1860. In psychiatry, the use of a systematic differential diagnostic method was first suggested by Emil Kraepelin, in early decades of the twentieth century, in the attempt to fragment the unitary concept of 'psychosis' into his classical dichotomy between the two major psychiatric syndromes (i.e., dementia praecox and manic-depressive illness). Kraepelin overtly declared that he wanted to abandon the classical 'symptomatic' view of mental illness to embrace a more 'clinical' method for classifying and diagnosing insanity. This probably represented the first attempt, in medicine, to overcome the crucial role of external clinical signs and subordinate it to consideration of the conditions of origin, the course, and the terminus which result from individual disorders.

Along the first half of the twentieth century, research in psychopathology continuously addressed the issue of classifying and differentially diagnosing psychiatric conditions. However, the impact of such research on clinical practice was rather small and most psychiatrists diagnosed their patients mostly based on their *gestalt*, or clinical impressions. Thus it is not surprising that, before the 1970s, psychiatric diagnoses were considered as alarmingly imprecise. There was some broad agreement on the core symptoms of the major syndromes, and this was reflected internationally in textbook descriptions. It was generally agreed, for example, that the characteristic symptoms of schizophrenia were thought disorder, flattening of affect and delusions, and hallucinations of particular kinds, and that some patients also exhibited other typically schizophrenic symptoms such as apathy and stereotypies; there was no agreement, however, on which combinations of these symptoms were adequate to establish a diagnosis of schizophrenia. Indeed, that question was almost never posed, and different schools of psychiatry and individual psychiatrists made different assumptions, and in practice trainee psychiatrists learnt how to diagnose syndromes such as schizophrenia and mania largely by modeling themselves on their teachers. As a result, several studies of the reliability of psychiatric diagnoses in the 1960s found the reliability of the diagnoses even of experienced psychiatrists to be distressingly low. As a consequence, most psychiatric syndromes appeared to merge into one another, or into normality, with no point of rarity in between. This means that the boundaries between syndromes (as well as those between disorder and normality) could have been considered rather arbitrary and that even small changes in the position of those boundaries, produced by minor changes in definition, may result in a change of diagnosis for a substantial number of subjects, both in prevalence surveys and in clinical practice. Problems in differential diagnosis were therefore very common, at that time, and probably insoluble without prior agreement on definitions (which, in the absence of any external validation, were necessarily arbitrary).

In order to scientifically address the issue of psychiatric classification and differential diagnosis, along the 1970s, the US/UK Diagnostic Project and the World Health Organization's International Pilot Study of Schizophrenia confirmed major between-country differences in the usage of key diagnostic terms such as 'schizophrenia' and 'manic-depressive illness,' and even between different cities or teaching centers in the same country. As soon as this chaotic situation became apparent it was agreed by the clinical research community that operational definitions were required, at least for all the major

syndromes (*see* Nosology in Psychiatry). Essentially, an operational, or semantic, definition is a statement or set of statements that spells out precisely which combinations of symptoms and behaviors are adequate to establish the diagnosis in question.

The Use of Operational Criteria for Differential Diagnosis in Psychiatry

The first set of 15 operational definitions for use in clinical research was published by the Department of Psychiatry of St. Louis University in the USA (Feighner et al., 1972). Other rival sets quickly followed: in the 1970s, the two major psychiatric diagnostic systems (namely, the *Diagnostic and Statistical Manual of Mental Disorders* – DSM, by the American Psychiatric Association, APA; and, the *International Classification of Diseases* – ICD, by the WHO) adopted a set of operational definitions of psychiatric syndromes. In the third edition of DSM (DSM-III; APA, 1980), the APA provided operational definitions for more than 200 psychiatric syndromes and demonstrated (by means of the field trials conducted before the glossary was published) that these operational definitions made it possible to achieve much higher levels of reliability than had previously been attained. Subsequently, the WHO provided similar operational definitions for most of the mental disorders listed in the tenth revision of the *International Classification* (*ICD-10*) (WHO, 1993).

The general recognition, at least by clinical research workers and epidemiologists, of the importance of operational and standardized diagnostic criteria in clinical psychiatry had a great impact on psychiatric diagnosis and differential diagnosis. The incorporation of precise diagnostic criteria sets into the major diagnostic systems aimed to improve the reliability of psychiatric diagnoses and to eliminate (or at least make overt) what were previously widespread, unrecognized differences in the diagnostic process. Reliability is now much higher and the unrecognized differences in diagnostic criteria between different countries and schools, which had caused so much confusion previously, have either been eliminated or, if different operational definitions are being used, the differences are now overt and explicit. However, the standardized operational diagnostic approach was originally conceived for research purposes. When applied to psychiatric clinical settings, operational diagnostic methods also created some controversies and deeply influenced the differential diagnostic process in psychiatry.

The Consequences of Definition by Operational Criteria

There are a number of fundamental problems arising from the fact that most mental disorders are defined by their clinical syndromes. The most important is that there is no scientific way of deciding which of two or more alternative operational definitions of a single disorder is correct, or even which is the best. In the case of most psychiatric disorders, there is no comparable external criterion to appeal to, because the clinical syndrome is itself the defining characteristic; this is why alternative operational definitions of disorders such as schizophrenia and agoraphobia remain in widespread use, side by side, and it is commonplace for individual patients to meet one of these definitions but not the other. A patient with typical schizophrenic symptoms for the past 6 weeks, for example, might well meet the formal criteria for schizophrenia in *ICD-10*, but not the corresponding criteria in later edition of *DSM* (DSM-5; APA, 2013); because the latter require evidence of continuous signs of illness for at least 6 months. In practice, this means that discussions about diagnosis need to take place in a context in which it is agreed which diagnostic system is being used, and also with a clear recognition of the fact that the choice between alternative sets of definitions is arbitrary.

Single versus Multiple Diagnoses

In medicine, as a whole, an attempt is generally made to explain all the patient's symptoms with a single diagnosis, and to try to avoid multiple concurrent diagnoses. The rationale for this is that several important diseases (e.g., infections, such as tuberculosis and syphilis) can affect many organs in the body and the correct diagnosis is more likely to be made if the physician consciously strives to account for all the patient's apparently unrelated problems with a single unifying explanation. In fact, people often have several different things wrong with them simultaneously, particularly as they age.

The same attempt to avoid multiple diagnoses is apparent in psychiatric practice, and the underlying rationale is similar. Patients are commonly given two diagnoses simultaneously if one is a lifelong state (such as mental retardation or a personality disorder) and the other an illness with an identifiable onset and a distinctive course (such as schizophrenia or depression). A diagnosis of some form of substance misuse is also commonly combined with a wide range of other diagnoses. There is a deep-seated reluctance, however, to diagnose a neurotic or stress-related disorder in the presence of psychotic symptoms such as delusions and hallucinations, despite the fact that psychotic and neurotic symptoms commonly coexist, and there is a similar reluctance to diagnose any kind of nonorganic psychosis if there is evidence of any brain disease. There is an even greater reluctance to diagnose two psychotic disorders simultaneously, or a mood disorder and a neurotic disorder simultaneously, despite the fact that depression and anxiety commonly coexist.

Hierarchy of Diagnoses

The reluctance to make multiple diagnoses corresponds to the attempt to set, in psychiatry, a diagnostic hierarchy. Karl Jaspers, more than a century ago, first tried to delineate such a hierarchy: in his *General Psychopathology* (Jaspers, 1913), he considered that only psychological disorders accompanying known cerebral pathology were "true disease entities," and within the group of schizophrenia and affective psychoses the diagnosis "has no specific alternative character. Either it is clear as a whole or the differential diagnosis over details determines nothing." To date, organic disorders still come at the top of psychiatric diagnostic hierarchy. This means that if the patient has clear evidence of

a brain disease – a tumor, for example – it is legitimate for them to have a wide range of other psychiatric symptoms, psychotic or neurotic, without any other diagnosis being required. Next in the hierarchy, come the so-called functional or nonorganic psychoses. If the criteria for one of these disorders – schizophrenia, for example – are met, the patient may also be depressed or anxious, or have phobic or obsessional symptoms, without any additional diagnosis being required. They must not, however, have evidence of overt brain disease. Neurotic and stress-related disorders usually come at the bottom of the diagnostic hierarchy, which means that diagnoses at this level cannot normally be made if psychotic symptoms or evidence of brain disease are also present. It is no accident, either, that this is the sequence in which disorders are listed in contemporary diagnostic manuals, and also the sequence of the decisions required by the flowcharts of computer programs for generating diagnoses from clinical ratings.

The requirements of this hierarchy are only relevant if the symptoms in question all appear at much the same time. But, if two groups of symptoms have a quite different time course from one another, it may be both legitimate and appropriate to make two independent diagnoses. In the past the diagnostic hierarchy used to be implicit rather than explicit. Now it is built into the operational definitions of individual disorders. At the same time, it has become more complicated, particularly in situations where schizophrenic and affective symptoms coexist, or follow one another in quick succession.

It is also still uncertain whether the hierarchy is simply an artifact, a device for reducing multiple diagnoses to a minimum, or whether it is a reflection of a fundamental characteristic of psychiatric symptomatology. It is certainly true that a high proportion of people with psychiatric symptoms, but not all, move up and down the hierarchy as they relapse and remit. For example, phobic and obsessional symptoms almost invariably become more widespread and severe if depressive symptoms develop; similarly, the development of hallucinations and delusions is usually accompanied by affective and neurotic symptoms which do not wane until after the hallucinations and delusions have disappeared.

The Boundary Problem

There is an old axiom that the art of classification consists in 'carving nature at the joints.' This is an elegant way of saying that a good, or a valid, nosology places the boundaries between adjacent disorders, and between these disorders and health, where there are genuine discontinuities, either in symptomatology or in etiology. If the defining characteristic of the disorder is a fundamental biological abnormality of some kind it may be self-evident that a discontinuity is involved. An additional chromosome or an abnormal gene, for example, clearly involve qualitative deviations from normality. If, however, the defining characteristic of the disorder is still its syndrome, or a quantitative deviation of some kind, such as a raised blood pressure or a raised blood level of thyroxin, it is not self-evident that there is a valid boundary between the syndrome in question and normality, or between this syndrome and others. Indeed, the fact that there are several rival operational definitions for many mental disorders, each of them encompassing slightly different populations of patients, strongly suggests that it is not obvious where the boundaries of those syndromes should be drawn.

Ideally, a 'point of rarity' between each syndrome and its neighbors needs to be demonstrated (Kendell, 1975). For example, it is widely assumed that schizophrenic and affective psychoses are distinct conditions. Indeed, the distinction Kraepelin drew at the end of the nineteenth century is still regarded as a fundamental feature of our contemporary classification of mental disorders; however, the so-called 'schizoaffective' patients (i.e., patients who present with a mixture of schizophrenic and affective symptoms) are quite common does not prove that there is no genuine boundary between the two syndromes, provided that these mixed forms are less common than the pure forms. The 'grays' must be less common than the 'blacks' and the 'whites'; or to express the issue graphically, the distribution of symptomatology along an axis extending from typical schizophrenia through schizoaffective states to typical affective psychoses must be bimodal rather than unimodal (see Figure 1).

An alternative to demonstrating discontinuities in the distribution of symptomatology is to identify a discontinuity in the relationship between symptomatology and some other important variable, such as prognosis or response to treatment. For example, it is well established that, on average, the outcome of affective psychoses is much better than that of schizophrenic illnesses, both in the short and the long term. The key issue, however, is not whether the two disorders have a significantly different outcome, but whether, when the variation in symptomatology is portrayed as a linear dimension (as described above) there is a discontinuity at some point in the relationship between symptomatology and outcome, or whether there is simply a linear improvement in outcome as the symptomatology becomes increasingly more affective (see Figure 2).

To date, most attempts to demonstrate valid and clear-cut boundaries by the psychiatric diagnostic categories failed and yet there is no empirical evidence at all for natural boundaries between major psychiatric syndromes and no one has ever found a set of symptoms, signs, or tests that separate mental

disorders into nonoverlapping categories. For example, the attempts to demonstrate a valid boundary between endogenous and reactive depressions were unsuccessful; when representative populations of patients were studied the distribution of individual patients along the discriminant function was consistently unimodal, rather than bimodal; partly for this reason, contemporary diagnostic manuals such as *ICD-10* (WHO, 1993) and *DSM-5* (APA, 2013) no longer include such a distinction. Similar attempts to demonstrate a valid boundary between schizophrenic and affective psychoses, either in symptomatology or in the relationship between symptomatology and outcome, were also unsuccessful (but a bimodal distribution of scores was subsequently demonstrated on a linear function discriminating between schizophrenia and all other psychiatric disorders combined). Finally, the attempt to identify a valid boundary between major depression and normality by demonstrating a discontinuity in the relationship between depressive symptomatology and either outcome or concordance between 1000 twin pairs also ended in failure (Kendler and Gardner, 1998).

The Consequences of Failure to Validate Boundaries

Cumulatively, the failure of most of these attempts to demonstrate valid boundaries between psychiatric syndromes emphasizes that it is unsafe to assume that there are valid boundaries to be found. We must take seriously the possibility that we are not yet 'carving nature at the joints,' or even that there are no 'joints' there, and that we are trying to impose an artificial set of discrete categories on what is in reality a continuous variation. Despite many proposed candidates, no single biological marker has been found to be specific for any operationally defined diagnostic category; also pharmacological trials proved, along the years, that psychotropic drugs are largely unspecific and that their action cuts across the categorically defined syndromes.

This state of affairs holds several important implications also for the differential diagnosis of psychiatric disorders. The first is the importance of recognizing that most of the categories of disorder recognized in contemporary nosologies have not yet been adequately validated, and that their formal definitions are simply agreed conventions. The second is a consequence of the first: all decisions about diagnosis and all discussions about differential diagnosis should take place in a setting in which it is agreed which set of diagnostic categories and corresponding set of operational definitions (in effect, which diagnostic system) are being used and with a clear understanding that both the categories and the definitions are arbitrary and inadequately validated, and therefore likely to be modified as understanding of the underlying etiology accumulates. The third implication is a consequence of the likelihood that many existing boundaries, either between syndromes or between psychiatric disorder and health, are not situated at points of rarity in the distribution of symptomatology. To the extent that this is the case, relatively minor changes in the operational definition of a syndrome, which produce corresponding changes in the position of its boundaries, may result in quite large changes in the numbers of people, or patients, who fall within those boundaries. This is almost certain why small changes in the definition of common disorders such as major depression or generalized anxiety – particularly changes in the number of typical symptoms required, or in their duration – have been associated with major changes in the recorded prevalence of these disorders in community surveys.

Finally, if it is indeed the case that there are no genuine boundaries within large tracts of the territory of psychiatric disorders, and we are imposing an artificial set of discrete categories on what is in reality continuous variation, psychiatrists will have to consider seriously the possibility of replacing their traditional categorical classification of disorders with a dimensional classification. This would never be done lightly, if only because the rest of medicine has always been committed to and content with categorical classifications of its disorders. If a dimensional format ever were to be adopted for mental disorders, however, the consequences for differential diagnosis would be profound. Disputes about which disorder or combination of disorders an individual was suffering from would be replaced by discussions about the precise locus in a multidimensional space at which that individual should be located. These discussions would probably also be calmer than the previous disputes, because in most cases it would be clear that the alternative loci under discussion were all quite close to one another, and not separated by dividing lines implying major differences in treatment or prognosis.

Practical Issues in Differential Diagnosis

As in other branches of medicine, some differential diagnoses are more critical than others in psychiatry. The most important functions of a diagnosis are to determine treatment and to predict outcome, and the most important differential diagnoses are those involving a disorder requiring urgent and specific treatment. All psychiatrists are keenly aware of the importance of diagnosing, or at least suspecting, cerebral tumors, and other brain diseases such as viral encephalitis and subdural hematoma, which may also present with psychiatric symptoms, as quickly as possible. Because these conditions may all present with depressive symptoms, with apathy or other behavioral changes, or even with psychotic symptoms, and because they all require urgent treatment, they enter into the differential diagnosis of a wide range of psychiatric disorders. Many reputations for diagnostic acumen are, rightly, based on successful detection of relatively uncommon brain diseases of this kind, or of metabolic disorders such as thyrotoxicosis and Cushing's syndrome, which underlie some anxiety states and depressions. It is also important to detect brain diseases such as Creutzfeldt-Jakob disease, which sometimes present with psychiatric symptoms even though there is not yet any treatment capable of altering the course of the disease, because of the implications for prognosis. If someone has an illness which is inevitably going to result in permanent disability or death, the sooner that is established the better, both for the patient and the family.

There are other circumstances in which the critical diagnosis in the differential diagnosis between brain disease and psychiatric disorder is the latter rather than the former. Dementias are common in old age and most are associated with progressive decline to dependency and death. Sometimes, however, depressive illnesses present with such widespread evidence of intellectual impairment that they closely resemble a dementia. Because depressions are eminently treatable it is vital that these 'depressive pseudodementias' are quickly recognized and treated, and depression is therefore an important part of the differential diagnosis of dementia. Similar considerations apply to rare curable dementias, such as those associated with a deficiency of thyroid hormone or vitamin B_{12}.

Traditionally, much time and intellectual effort have been devoted by psychiatrists to distinguishing accurately between schizophrenic and affective psychoses. To some extent this is appropriate. The two disorders require different treatments and there are major differences in long-term prognosis between them. Some disagreements are due simply to undisclosed differences in diagnostic criteria which would be resolved by the adoption of an agreed operational definition. However, a more fundamental conceptual issue may also be involved. Although there are many instances, including the differential diagnosis between schizophrenic and affective psychoses, where no valid boundary has yet been demonstrated between the two syndromes, psychiatrists often still behave as though they were discussing the distinction between two 'disease entities.' In reality, if the patient's symptoms are 'schizoaffective,' it may not matter much which side of an arbitrary boundary they are deemed to lie, because their therapeutic needs and their prognosis may both be genuinely intermediate between those of the two classical syndromes.

To diagnose schizophrenia is always a grave decision. Although some people develop schizophrenic illnesses which resolve completely, even without treatment, and never recur, for many more a schizophrenic episode is the prelude to a life of invalidism and the death knell of hopes and ambitions. It is understandable; therefore, that many psychiatrists are reluctant to diagnose schizophrenia, particularly in an adolescent, unless the evidence is incontrovertible. If some less doom-laden diagnosis, such as depression, is plausible they will opt for that, and hope that time will justify their decision. Recently, however, psychiatrists have become increasingly convinced by the evidence that early treatment with neuroleptics improves the long-term outcome of schizophrenic illnesses and reduces the risk of a 'defect state.' Although this evidence is not yet buttressed by random allocation trials it is sufficiently strong to swing the balance of advantage in patients with ambiguous symptomatology in favor of early diagnosis. A similar mix of social and therapeutic considerations has an influence on differential diagnosis in other areas too.

Other important issues of differential diagnosis arise when patients with psychiatric disorders present to other medical disciplines, as they commonly do. Depressive illnesses are extremely common at all ages and depressed patients may present with a wide variety of complaints, particularly if they are reluctant to accept that they may have a psychiatric disorder. They may complain of 'feeling off color,' of loss of appetite or weight, of difficulty sleeping, or of ill-defined pain almost anywhere in the body. As a result, the correct diagnosis is often missed unless questions are asked about characteristic depressive symptoms such as difficulty concentrating or loss of the ability to enjoy things. Phobic anxiety is another common disorder which often presents with somatic symptoms such as palpitations, or recurring bouts of upper abdominal discomfort or difficulty breathing. Unless specific questions are asked about the environmental circumstances in which these symptoms develop, their phobic nature may easily be missed and the patient may be subjected to a long series of irrelevant investigations. In both cases the fundamental problem is that the doctor concerned does not realize, or remember, that a depressive illness or phobic anxiety should be important elements in the differential diagnosis of the patient's presenting complaints, even though these may be entirely somatic.

Finally, a possible aftermath of the spread of categorical-operational approach to psychiatric diagnosis is the popularity recently gained by the concept of 'psychiatric comorbidity' (i.e., the coexistence of two or more psychiatric diagnoses). Several warnings (see Maj, 2005) have been recently made that the increased recognition of comorbid psychiatric diseases may just represent a by-product of the introduction of the latest version of ICD and DSM: since their adoption in clinical settings, the idea that psychiatric disorders represent discrete disease entities has been significantly questioned and the process of differential diagnosis since, according to this view, the nature of psychopathology might just be intrinsically composite and changeable and the idea splitting syndromes into multiple disorders could be just a nonvalid approach to the complexity of psychiatric conditions.

Differentiation: Social

Abstract

The concept of social differentiation is an important theoretical instrument to understand the origin, dynamics, and structure of modern society. In sociological theory, there are two perspectives on the differentiation of modern society. On the one hand, social differentiation is seen as division of labor, with an emphasis on advantages of specialization. On the other hand, social differentiation is understood as the emergence of autonomous 'value-spheres' or self-referential chains of communication, with an emphasis on the 'polycontexturality' of society. Performance improvements, evolution, the rationalization of cultural ideas, and interests of actors are identified as driving forces of social differentiation. The consequences of increasing differentiation are ambivalent both for individuals and for society at large. Individuals gain options but lose 'ligatures'; and modern society pays for performance improvements of its subsystems with problems of social and ecological integration.

Social differentiation is an important attribute of society, especially modern society (*see* Societies, Types of). The concept of differentiation spread within sociology since Herbert Spencer's evolutionary theory of societal development 'from incoherent homogeneity to coherent heterogeneity.' Later on, Emile Durkheim, Georg Simmel, Talcott Parsons, and Niklas Luhmann were important proponents of the concept. Other social thinkers, such as Karl Marx and Max Weber, who did not use the term 'differentiation' prominently nevertheless contributed to a proper understanding of the social structures and dynamics it designates. At the start of the twenty-first century, the theoretical and, more and more, empirical debate about social differentiation is continued, especially by American 'neofunctionalists' in their discussion of Parsons' legacy and by some German sociologists who keep up the debate based on Luhmann or Weber (Alexander and Colomy 1990; Schimank 1996; Schwinn 2011).

Social differentiation means both a process and a structure. In structural terms, it refers to the fact that a unit of analysis, such as a society, consists of a number of distinct parts. These parts may be of the same kind, such as families as the basic components of tribal societies. Or the parts may be different, such as the subsystems or 'value-spheres' – economy, politics, mass media, etc. – making up modern society. As a process, social differentiation is the dynamic that brings about and changes a given structure of differentiation.

Two fundamentally diverging views of the social differentiation of modern society have been put forward in sociological thought. In the following, the partly opposing but mostly complementary relationship between both views will be sketched, with respect to the features, driving forces, and consequences of social differentiation. The focus of attention will be put on the differentiation of modern society.

Social Differentiation as Decomposition or Emergence

For Durkheim and Parsons as the most important representatives of the first view of social differentiation, it is a process of decomposition of a functionally diffuse unit – a role or an institution – into several, functionally more specific units. This idea is modeled after the division of labor in work organizations, a process which fascinated nineteenth-century thinkers (*see* Labor, Division of). Durkheim's major illustration is the widespread specialization of occupations in industrial society. In Parsons' (1971) more abstract analysis, society is composed of four principal subsystems (economy, polity, societal community, and fiduciary system) each of which fulfills one of the four fundamental functional prerequisites of societal reproduction. Social differentiation as a process of social change tends toward a successive decomposition of each of these subsystems into four second-level subsystems, and so on. Parsons called this 'functional differentiation,' a term that is still used to describe the type of differentiation of modern society. His analytical perspective, Parsons suggests, is validated empirically over time by the concrete differentiation of social roles and institutions.

In structural terms, the decomposition perspective on social differentiation highlights the advantages of specialization for society, which are basically the same as on the organizational level. Specialization greatly improves performance. For instance, if formal education in schools is differentiated from the family, where education was previously concentrated, both sides profit in terms of functional efficiency and effectiveness – teachers can rely on primary socialization accomplished by parents and are able to focus on secondary socialization, and vice versa.

In contrast to this perspective of social differentiation as an overall harmonious division of labor, Weber portrayed the birth and composition of modern society as the emergence of a number of autonomous 'value-spheres.' One after another, science, law, art, politics, economics, sexuality, and others freed themselves from their former domination by religious ideas. These value-spheres became societal domains of their own which cultivate their particular central value without concern for the value orientations of other domains. Science, for instance, does not care about economic profits, aesthetic beauty, legality, or the conformity of its truths with religious

doctrine. Weber (1919, pp. 27–28) speaks graphically about the 'polytheism' of value-spheres in modern society.

Luhmann formulates this second perspective on social differentiation even more to the point. To him, society consists of about a dozen subsystems in each of which communication is guided by a specific binary code. For example, the science system's binary code is true/untrue, the legal system's legal/illegal. The binary code of each subsystem establishes a highly selective searchlight onto the social world, illuminating certain corners of it and leaving the rest in the dark.

The binary codes generate self-referentially closed universes of communication. Thus, a societal subsystem consists of chains of communications each of which refers to other communications of the same kind. For this fundamental feature, Luhmann picks up the concept of 'autopoiesis' from biological thinking (*see* Sociobiology and Sociology: A New Synthesis). To illustrate, in the social system of science, assertions of truth are the specific kind of communication. These assertions, usually made in scientific publications, lead to other such assertions, and – within science – not to political declarations or declarations of love. Any scientific publication, if it provokes any reactions at all, is either affirmed or rejected by later publications. Which of these two eventualities happen does not matter with respect to the reproduction of science as a societal subsystem. In both instances, science continues as an open-ended sequence of publications.

Luhmann's conceptualization is better suited than Weber's to grasp the basic dynamics of continual reproduction of a societal subsystem or value-sphere. For Luhmann, each subsystem can take only its own code-determined perspective on social events. In science, nothing but its own concerns are important, and the same holds true for all other subsystems. The overall result is an effective multiplication of society with respect to the communicative meanings of events. An event, such as a train accident, looks totally different from the point of view of the economy, compared to the points of view of science, health care system, mass media, and so on. Borrowing a term from philosopher Gotthard Guenther, Luhmann (1997) calls this the 'polycontexturality' of modern society, which is very near to Weber's 'polytheism.'

Although all subsystems have, in this sense, no 'window' to the social world outside, this basic autonomy goes along with an openness to their societal environment with respect to resources and functional performance. The science subsystem, for instance, needs financial resources among other things, and gets them from the political subsystem, or the economy. In the other direction, science provides these and other societal subsystems with knowledge. Since all societal subsystems make essential contributions to the reproduction of many others and none of them can substitute any other one, each is a functional prerequisite of modern society. Modern society would break down without economy, but also without mass media, or without a health care system, and the latter could not be replaced, for example, by politics or education.

Despite these manifold mutual dependencies which Parsons conceives of as "double interchanges," Luhmann insists that it makes no sense to understand the ensemble of societal subsystems as a division of labor. In a division of labor, the subsystems as parts are teleologically oriented toward the performance and maintenance of the whole society. Thus, the whole comes first, historically and logically, and decomposes itself for its own benefit. By contrast, Weber and Luhmann emphasize that social differentiation consists of a simultaneous birth and liberation of the parts. They emerge and at the same moment become autonomous from each other and from the whole. Even more, the whole vanishes in the sense that it becomes nothing more than the – often tension-ridden and antagonistic – interrelationship of the parts.

Driving Forces of Social Differentiation

Both analytical perspectives identify different driving forces of social differentiation. Four kinds of causal factors can be distinguished: improvements of performance, evolution, cultural ideas, and interests of actors.

The first causal factor, improvements of performance by specialization, was especially emphasized by Parsons and structural–functionalist studies of social differentiation (*see* Functionalism in Anthropology). Such specialization is initiated either by performance deficits of existing structures or by opportunities to improve a satisfactory level of performance. An example of the problem-driven dynamic is the previously mentioned differentiation of the education system. Schools, and a duty of all children to attend them, were established because other societal subsystems, especially the economy, needed a general level of cognitive skills and social discipline within the population that could no longer be provided by the family alone. A dynamic driven by opportunities was the spur for differentiation of the radio and television sector within the mass media. Entirely new possibilities of public communication opened up by the technological innovations of radio and television, rather than any perceived performance deficits of newspapers, caused the sectoral differentiation of roles and organizations within mass media.

By contrast to a planned division of labor within organizations, on the societal level performance improvements by differentiation occur often as unintended results of actions motivated by quite different reasons. In this sense, Parsons already relied on evolution as the mechanism that brings about performance improvements (*see* Evolutionary Sociology). In contrast, Luhmann gives up all connotations of evolution with progress. Adopting neo-Darwinian evolutionary thinking from biology, he conceives of evolution as an interplay of three mechanisms, variation, selection, and retention. Each societal subsystem has its own specific evolutionary mechanisms. For instance, in the science subsystem, most publications are variations of the existing body of knowledge. Selection happens whenever one of these publications is cited affirmatively. Retention occurs when this new knowledge is incorporated into overview and review articles and into textbooks for students. As in biological evolution, most variations are not selected, and most of those selected do not reach the stage of retention. This evolutionary cognitive growth and differentiation goes along with a social differentiation of scientific specialties.

Luhmann does not deny that this evolution of the science system may bring about performance improvements usually called 'scientific progress.' But for him, this is no necessary outcome of evolutionary differentiation. Evolution may

also lead to dysfunctional differentiation. For instance, the growing quest for interdisciplinary research indicates an overspecialization in more and more scientific fields. An understanding of evolutionary differentiation as progress becomes even more dubious in other societal subsystems, such as art, politics, or the mass media. But even if evolutionary differentiation on the level of each subsystem would produce performance improvements of all of them, the overall result for society would not add up to progress but only to an increase of societal complexity which manifests itself particularly in a growing destabilization of society. Each evolutionary change within one subsystem is also a change of the societal environment of all other subsystems. For them, often adaptive changes become necessary each of which again changes the societal environment, with new adaptive pressures arising. Thus, social differentiation becomes permanently autodynamic. Until now, these dynamics often brought about increasing differentiation. But Parsons' statement that this is a linear and unlimited social process is clearly wrong as pointed out by Luhmann's theoretical reflections and demonstrated by the empirical cases presented especially by the neofunctionalists.

A third driving force of social differentiation was already mentioned with respect to Weber: an autodynamic rationalization of cultural ideas. In premodern societies, the values that today constitute the guiding principles of the various societal subsystems were closely interwoven with each other and, moreover, integrated into an encompassing order of religious values. The differentiation of the principal subsystems of modern society is understood by Weber as a gradual but irresistible separation of economic, political, scientific, aesthetic, legal, erotic, and other values, first, from the religious context, and second, from each other. This dynamic is triggered and sustained by the compelling intellectual urge to contemplate extensively the implications and consequences of each value for everyday life. When this rationalization reaches the point where each value is rigorously reflected in its own terms, without regard to others, soon a self-referential closure of value-spheres occurs, giving way to a corresponding differentiation of roles, organizations, and subsystems.

The fourth driving force of social differentiation is the general interests of individual, collective, or corporate actors (*see* Interests in Sociological Analysis). One explanation of an ongoing division of labor mentioned by Durkheim (1893) is growing 'social density' resulting in an intensification of competition among actors. This constellation evokes an interest to preserve one's own domain of action, be it an occupation for an individual or a market position for a firm. This interest, in turn, leads many of the respective actors to find new niches for themselves where they are relieved from high competitive pressure. The aggregate effect of such domain-preserving activities is social differentiation on the level of roles and organizations.

Other general interests of actors that often stimulate dynamics of social differentiation are the preservation or extension of one's autonomy, of one's control of other actors, and of one's resource base. Some professions, especially those guided by such interests were strong carriers of the differentiation of certain societal subsystems including science, law, education, and health care (*see* Professions, Sociology of). Sometimes, a particular kind of social differentiation is the explicit goal of certain groups of actors who believe that this will serve their interests best. In other cases, social differentiation is an unnoticed, unforeseen, or unwanted effect of actors' pursuit of their interests. Outcomes often diverge markedly from intentions because usually the relevant constellation consists of actors in quite different positions: catalyzers and promoters of the respective process of change; followers who join in when a 'critical mass' has been mobilized; defenders of the status quo who resist any change; more open-minded defenders with whom compromises are possible; and those who are indifferent or indecisive at the beginning and whom the promoters of change as well as the defenders of the status quo try to recruit as allies.

Each of these four kinds of driving forces is causally relevant in the dynamics of social differentiation, although the combination varies greatly from one case to another. Often these factors are interrelated. Thus, what actors understand as their interests is framed by cultural ideas. Cultural ideas as well as actors' interests are explicit or implicit criteria to judge the performance of a given differentiation structure; and on the other hand, performance deficits provoke actors' interests. Finally, the evolution of societal subsystems creates new challenges, restrictions, and opportunities for the pursuit of interests and the spelling out of cultural ideas.

Consequences of Social Differentiation

The differentiation of modern society became a central theme not just of sociological thought but also of public discourse in the nineteenth century, and still is today. This is because social differentiation has far-reaching consequences for society at large, as well as for each individual member of it. These consequences are neither totally positive nor totally negative but a mixed blessing.

To begin with, the modern individual profits from role differentiation and an enormous increase of options in every sphere of life, from economic markets for goods and services to opportunities of political participation, sports activities, lifelong education, and cultural life. The abundance of options is the result of performance improvements in all societal subsystems and of an inclusion of all members of society into the status of customers, clients, and public of the subsystems. In connection with the polycontexturality of modern society, role differentiation and the growth of options allow each person to become an individual in the proper sense of the word: a person who creates a unique biography for himself or herself. However, options are only one side of a person's 'life chances' (Dahrendorf, 1979). The other side includes 'ligatures,' meaningful attachments which tie a person to certain institutions, cultural worlds, social groups, or communities. In this respect, the functional differentiation of modern society seems to neglect important psychic needs of persons. Ligatures are eroded by 'polycontexturality' and individualization. As a consequence, anomy, alienation, and other experiences of meaninglessness are present in modern society, not just as individual misfortunes and temporary phenomena, but as structurally produced permanent vulnerabilities of everyone.

Looking at the society at large, social differentiation exhibits the same kind of ambivalence. First, it is obvious that functional differentiation is evolutionarily highly successful. All kinds of premodern, traditional societies were overrun by those national societies from Europe and North America that converted to functional differentiation since the sixteenth century. Worldwide, there was no alternative to the adoption of functional differentiation. As shown by the socialist experience, those countries that tried to stop halfway failed. Countries where the political system attempted to control all other subsystems were beaten by the fully developed functional differentiation of Western countries, as Parsons, among others, had anticipated in the 1960s.

However, global supremacy of a fully fledged functional differentiation implies serious problems. Their common denominator is an endangering of the integration of modern society. More precisely, systems integration, social integration, and ecological integration must be distinguished.

Systems integration refers to the coordination and cooperation among different subsystems of modern society. This is obviously possible, despite the fact that each of them is governed by its own self-referential binary code. There are manifold interrelationships by which subsystems adapt to each other in a decentralized way. Where this does not suffice, representatives of subsystems, such as the respective interest groups, meet and bargain for common solutions in the political arena. Finally, political guidance may support or promote intersystems adaptation and bargaining among subsystems. Thus, problems of systems integration most of the time remain fragmented and manageable in modern society. However, contemporary pressures of 'economizing' on many other societal subsystems such as health care, education, or science are a serious challenge to the maintenance of their autonomy.

Social integration means the integration of individual members into modern society (*see* Integration, Social). It may be precarious as a result of the already mentioned erosion of ligatures. More important could be the fact that the increase in individual options might put excessive demands on all subsystems' abilities in the long run. In this respect, social inequality and the subsystems' unlimited drive to improve their performance work hand in hand (*see* Inequality, Social). In conflicts among those who, as individuals, profit more and those who profit less from a particular subsystem's performance, the former will try to avoid redistribution. One way to achieve this is a growth of the subsystem's performance so that those whose claims were not satisfied can be served somewhat better without those who were better of giving up anything. For instance, children from the lower classes have got access to higher education. But this has been no zero-sum conflict in which the higher classes have lost some of their educational opportunities but a positive-sum constellation because the higher education sector has been extended – which has fitted also the interests of the respective groups of teachers and professors and has been reinforced by the cultural imperative of 'progress.' Such dynamics could go on forever, were there no limits to subsystems' growth. But because these limits exist, for example with respect to financial resources, continuing inequalities contain a potential for serious social conflict to which functional differentiation has no ready answer. In fact, in many countries, social inequalities have grown again during the last three decades, and large parts of the world population are only minimally included and sometimes even totally excluded from most subsystems' services.

Finally, the functional differentiation of modern society is a major cause of the growing problems of ecological integration. Modern society's path away from a 'sustainable' relationship with its natural environment has occurred as a result of two basic characteristics of all societal subsystems: their growth tendencies and the neglect of ecological aspects by their binary codes. The modern economy is the most obvious example, but the same is true of the family, the subsystem primarily responsible for population growth. No societal subsystem exists now that takes care of the ecology, only social movements address their protest to the political system. But government, following its binary code of maintaining and increasing power, must listen to many other demands from society and so often disregards ecological concerns.

Thus, the functional differentiation of modern 'world society' is a high-risk outcome of social evolution. No alternative to this type of social differentiation is apparent as an option for the future. But whether modern society can survive in this way or will ruin itself sooner or later is an open question that sociological theories of social differentiation cannot answer. Theorists can only observe what has happened previously and infer warnings from this.

Abstract

Diffusion and random walk processes comprise one of the main classes of sequential-sampling models for decision making and choice response time in psychology. The models assume that decisions are made by accumulating samples of noisy evidence to a response criterion, either in continuous or in discrete time. The models successfully predict the main features of performance in speeded decision tasks: accuracy, the ordering of mean response times for correct responses and errors, the shapes of response time distributions, and the effect of instructions. Neural correlates of the evidence accumulation process have been identified in studies of the brain regions involved in decision making.

Historical Foundations

Diffusion and random walk models form one of two major classes of sequential-sampling models for speeded decision making and choice response time in psychology. The other class comprises accumulator and counter models. A taxonomy of these two classes of models, first compared by Audley and Pike (1965), is shown in **Figure 1**. Models of both classes conceive of decision making as a statistical process, in which successive samples of noisy evidence or stimulus information are accumulated to a response criterion. The evidence is assumed to be noisy, either because the stimulus is a sequence of variable or noisy events, or because of noisy coding in neural systems. The criterion represents the amount of evidence needed to make a decision. In random walk models, evidence for one response is evidence against the other. The accumulating evidence is represented as a single fluctuating sum, which increases or decreases as evidence favoring one or other response is sampled. In counter and accumulator models, evidence for the two responses is accumulated in parallel, in separate totals. The decision process in these models has the form of a race between accumulating evidence totals, with the winner of the race determining the response.

Figure 1 Sequential-sampling models. The branch on the left shows random walk and diffusion models. The hybrid accumulator–diffusion models shown under the branch on the right combine the attributes of accumulator models and diffusion models.

Random walk models are the discrete-time counterpart of diffusion process models and historically preceded them. Random walk models for decision making were introduced into psychology by Stone (1960) and Edwards (1965) and were developed subsequently by Laming (1968). The aim of the models was to provide a unified account of the processes underlying psychology's two ubiquitous dependent variables: accuracy and response time (RT). The early random walk models were influenced by Wald's (1947) sequential probability ratio test (SPRT) in statistics, which was based on the accumulation of log-likelihood ratios. SPRT models assume that the decision process acts on a sequence of noisy observations, each element of which provides evidence for one of two alternative hypotheses, H_a and H_b, which represent states of the world. In a choice response time setting, the hypotheses might be that either stimulus s_a was presented or stimulus s_b was presented. The task is to decide which of these hypotheses is true and to respond as quickly as possible. The evidence is represented as a sequence of random variables, Z_j, $j = 1, 2, \ldots$, which is sampled at a constant rate. The decision process computes the log-likelihood ratio of the evidence for the two hypotheses obtained at step j and accumulates these as a running sum. If $p_a(Z_j)$ and $p_b(Z_j)$ denote the probability density functions for Z_j under H_a and H_b, respectively, then the decision process, X_i, at time i is the sum,

$$X_i = \sum_{j=1}^{i} \log\left[\frac{p_a(Z_j)}{p_b(Z_j)}\right]. \qquad [1]$$

If the Z_j are Gaussian random variables, then the log-likelihood ratio is also Gaussian, and the running sum is a Gaussian random walk.

To make a decision, evidence is sampled until the accumulating total reaches or exceeds one of two absorbing boundaries or evidence criteria, a and b, with $b < 0 < a$. If the first criterion reached is a, the person makes response R_a (stimulus s_a was presented); if the first criterion reached is b, the person makes the alternative response R_b (stimulus s_b was presented). The decision time, T, is the minimum time to reach a criterion. Formally, if $T_a = \min\{i : X_i \geq a\}$ and $T_b = \min\{i : X_i \leq b\}$, then $T = \min(T_a, T_b)$. The time of the first boundary crossing, T, is guaranteed to be finite, which means that the process will terminate in finite time with one or other response. Wald's SPRT is optimum in the sense that it is the process that achieves a given criterion level of accuracy in the minimum expected time. It was this property that first recommended it as a model for decision making in settings in which there is a cost associated with sampling evidence, either in time or other units.

A later random walk model, the *relative judgment theory* of Link and Heath (1975), omitted the computation of likelihood ratios and assumed the walk accumulates the magnitudes of the noisy evidence sequence, Z_j, directly,

$$X_i = \sum_{j=1}^{i} Z_j. \qquad [2]$$

This change was to allow the model to account for the orderings of mean RTs for correct responses and errors that are found experimentally. Some recent treatments of random walks and diffusion processes in psychology and neuroscience have again begun to emphasize the connection with Wald's SPRT and optimality (Bogacz et al., 2006; Gold and Shadlen, 2002).

Diffusion Process Models

Mathematically, diffusion processes are the continuous-time counterparts of random walks. Whereas a random walk, X_i, accumulates evidence at discrete-time steps, $i = 1, 2, \ldots$, a diffusion process, X_t, accumulates evidence in continuous time ($t > 0$). The study of diffusion processes was begun in physics in 1905 by Albert Einstein, who derived a partial differential equation for the probability distribution of a pollen particle undergoing Brownian motion. He showed that this equation had the same form as the classical heat equation of physics (Gardiner, 2004). In 1923, Wiener began the mathematical study of the path-space properties of diffusion processes, by proving the existence of a continuous stochastic process whose transition distribution satisfied the partial differential equation derived by Einstein. The resulting process is variously known as the *Brownian motion process* or *Wiener diffusion process*.

Ratcliff (1978) proposed a diffusion process model of two-choice decision making in psychology, arguing that information processing in the brain is better viewed as a continuous-time rather than a discrete-time process. In his model, which is shown in **Figure 2**, the accumulating evidence is described by the diffusion process studied by Einstein and Wiener. The model is similar to the earlier random walk models in that it conceptualizes decision making as diffusion on a line between absorbing barriers, which represent decision criteria. Ratcliff's model follows the gambler's ruin framing of

Figure 2 Diffusion model. The process starting at z accumulates evidence between absorbing boundaries at 0 and a. Moment-to-moment stochastic variability means the process can sometimes terminate at the correct response boundary, R_a, and sometimes at the error response boundary, R_b. Drift rate, ξ, is normally distributed between trials with mean ν and standard deviation η. Starting point is assumed to be rectangularly distributed with range s_z. RT is the sum of the stimulus encoding time, u, the decision time, d, and the response output time, w. The nondecision time, $T_{er} = u + w$, is rectangularly distributed with range s_t.

the process of Feller (1967), in which the lower barrier is set to 0, the starting point is set to z, and the upper barrier is set to a. Evidence for one response drives the process in an upward direction; evidence for the other response drives it in a downward direction, with the process continuing until one of the absorbing boundaries is crossed and a response is made. Unlike those models, evidence in his model accumulates continuously rather than at discrete points in time.

Like relative judgment theory, the evidence accumulated in the diffusion model is assumed to be a sequence of noisy sensory or cognitive states, rather than a likelihood ratio transformation of those states. Because the accumulation process, X_t, in the model is Gaussian, and because the likelihood ratio of a Gaussian process itself has a Gaussian distribution, the accumulating evidence in the diffusion model is proportional to the log-likelihood ratio. Consequently, although the model does not assume a likelihood ratio transformation of evidence states, it is SPRT optimal in the same way as are the likelihood ratio models of Laming (1968) and earlier researchers (Bogacz et al., 2006).

Ratcliff (1978) emphasized the importance of other sources of trial-to-trial variability in the model, in addition to diffusive noise arising from moment-to-moment variability in the evidence entering the decision process. The effects of diffusive noise are shown as short-time-scale random fluctuations in the accumulating evidence in **Figure 2**. The other sources of variability reflect cognitive processes that affect the decision process on individual trials. The first of these, shown in **Figure 2**, is variability in the rate of evidence accumulation, or the *drift rate*, of the process, which is assumed to be normally distributed. Drift variability represents trial-to-trial variation in the average quality of the information entering the decision process and arises due to variations in the quality of the match between encoded stimuli and the decision alternatives in memory. The presence of drift variability means that on some trials the process will drift in the wrong direction (i.e., presentation of stimulus s_a will cause the process to drift toward the R_b boundary or vice versa). This allows the model to predict slow errors, which are often found experimentally when stimulus discriminability is low and accuracy is stressed.

Ratcliff et al. (1999) added another source of trial-to-trial variability, first proposed by Laming (1968), in the starting point of the process. Starting point variability also allows the model to predict fast errors, which are often found experimentally when stimulus discriminability is high and speed is stressed. Fast errors arise because responses on trials on which the process has started near the error response boundary are more likely to be made rapidly and incorrectly.

Ratcliff (1978) also initiated the study of RT distributions as a method for testing decision models. Most early model comparisons focused on the ordering of mean RTs for correct responses and errors and the relationship between mean RT and accuracy. Ratcliff showed that the properties of empirical RT distributions impose strong constraints on the class of plausible models and, moreover, that the Wiener diffusion model predicts the families of RT distributions that are found experimentally. This has been confirmed in numerous studies of speeded decision making in simple perceptual and cognitive tasks in a variety of settings (Ratcliff and Smith, 2004; Ratcliff et al., 2005).

Mathematical Methods for Diffusion Processes

Diffusion processes are continuous time, continuous state space, Markov processes. Members of the class of diffusion processes are defined by specifying the *infinitesimal moments* of the process, together with initial and boundary conditions. The infinitesimal moments are the *drift* and *diffusion* coefficients, which define, respectively, the mean rate of change and the variance in the rate of change in a unit interval. In a general diffusion process, the drift and diffusion can both depend on time and on the state of the process. For such a process, the drift, $\mu(x, t)$, and diffusion coefficient, $\sigma^2(x, t)$, can be continuous functions of the state variable, x, and the time variable, t. In Ratcliff's (1978) model, the drift and diffusion coefficients are both constant and are denoted ξ and s^2, respectively, where $\xi \sim N(\nu, \eta)$ and where $N(.,.)$ is the normal density function and the tilde means 'is distributed as.'

Mathematically, diffusion processes can be defined via either partial differential equations or stochastic differential equations. If $f(s, y; t, x)$ is the transition density of the process, that is, $f(s, y; t, x)\,\mathrm{d}x$ is the probability that a process starting at time s in state y will be found at time t in the interval $(x, x + \mathrm{d}x)$, then the general diffusion, X_t, satisfies the partial differential equation

$$-\frac{\partial f}{\partial s} = \frac{1}{2}\sigma^2(y,s)\frac{\partial^2 f}{\partial y^2} + \mu(y,s)\frac{\partial f}{\partial y}. \qquad [3]$$

This is the Kolmogorov backward equation, so called, because its variables are the starting time and state, s and y. The process also satisfies the forward equation, which is an equation in t and x. The backward equation is useful for deriving RT distributions; the forward equation is useful for studying evidence accumulation by a process unconstrained by absorbing boundaries (Ratcliff, 1978). Alternatively, X_t can be defined as satisfying the stochastic differential equation

$$\mathrm{d}X_t = \mu(X_t, t)\mathrm{d}t + \sigma(X_t, t)\mathrm{d}W_t, \qquad [4]$$

where W_t is the Brownian motion process.

The key properties of the process in modeling decision making are the first passage time probability and the first passage time distributions. The first passage time probability is the probability that the process reaches a specified one of the absorbing boundaries before reaching the other one. In the decision model, the probability of making a particular response, say R_a, is given by the probability that the process crosses the absorbing boundary a before it crosses the boundary b. If T_a and T_b are the first passage times for the boundaries a and b, respectively, then the probability of making response R_a is $P(R_a) = P[T_a < T_b]$. The first passage time distributions, denoted $G_a(t)$ and $G_b(t)$, are the distributions of T_a and T_b. In the model, the first passage times are the decision times for the two responses. If the stimulus presented was s_a, then $G_a(t)$ and $G_b(t)$ are the distributions of correct responses and errors, respectively. The converse holds if the stimulus presented was s_b.

A variety of methods exist in the literature for obtaining first passage time statistics for diffusion processes. Classically, partial differential equations like eqn [3] are solved as algebraic eigenvalue problems. When the diffusion is time homogeneous (i.e., the drift and diffusion coefficients do not vary with time), these methods yield the first passage time distributions in the form of infinite series, which can be approximated by truncation (Ratcliff, 1978). For a diffusion with drift ξ, diffusion coefficient s^2, and starting point z, where $b < z < a$, the probabilities of responding at the upper and lower barriers are

$$P(R_a) = \frac{\exp(-2\xi z/s^2) - \exp(-2\xi b/s^2)}{\exp(-2\xi a/s^2) - \exp(-2\xi b/s^2)}, \quad [5]$$

and

$$P(R_b) = 1 - P(R_a), \quad [6]$$

respectively. The first passage time densities, $g_a(t)$ and $g_b(t)$, defined as $g_a(t) = G_a'(t)$ and $g_b(t) = G_b'(t)$, where primes denote differentiation with respect to time (Smith, 1990), are

$$g_a(t) = \frac{1}{P(R_a)}\exp\left[\frac{\xi(a-z)}{s^2} - \frac{\xi^2 t}{2s^2}\right]\frac{\pi s^2}{(a-b)^2} \times \sum_{k=1}^{\infty} k\exp\left[-\frac{k^2\pi^2 s^2 t}{2(a-b)^2}\right]\sin\left[\frac{k\pi(a-z)}{a-b}\right] \quad [7]$$

and

$$g_b(t) = \frac{1}{P(R_b)}\exp\left[\frac{\xi(z-b)}{s^2} - \frac{\xi^2 t}{2s^2}\right]\frac{\pi s^2}{(a-b)^2} \times \sum_{k=1}^{\infty} k\exp\left[-\frac{k^2\pi^2 s^2 t}{2(a-b)^2}\right]\sin\left[\frac{k\pi(z-b)}{a-b}\right]. \quad [8]$$

In applications, it is often more convenient to work with first passage time distribution functions rather than densities. Ratcliff (1978) gave the distribution functions using Feller's (1967) gambler's ruin form of the process, in which the lower boundary is set to zero ($0 < z < a$).

Several other methods have been investigated for obtaining first passage time statistics for diffusion processes. These methods can be used for more complex problems, such as, for example, when either the drift and diffusion coefficients or the absorbing boundaries vary with time, for which classical methods for solving partial differential equations often do not yield tractable solutions. These include integral equation methods, originally developed to study models of integrate-and-fire neurons in mathematical biology (Smith, 2000), numerical methods for solving partial differential equations (Voss and Voss, 2008), and matrix methods (Diederich and Busemeyer, 2003). The matrix approach, which approximates diffusion processes with finite state Markov chains, can be applied to very general problems of the kind that sometimes arise in applications, such as multidimensional diffusions with correlated increments (Ditterich, 2006). Although such problems can be made theoretically tractable via the use of finite state approximations, the size of the transition matrix required to represent the process and the associated computational demands rapidly become large. Tuerlinckx et al. (2001) have investigated methods for simulating diffusion processes.

Ornstein–Uhlenbeck Models

Since Ratcliff's (1978) article, researchers have investigated a number of variations on the underlying model. Busemeyer and Townsend (1993) proposed a model based on the Ornstein–Uhlenbeck (OU) diffusion process. This process was proposed in 1930 by Uhlenbeck and Ornstein as an alternative model for Brownian motion to that of Einstein and Wiener (Gardiner, 2004). It sought to correct a perceived shortcoming of that model, namely, it implies the velocity of a diffusing particle is almost everywhere infinite. Rather than modeling the displacement of the particle, the OU process models its velocity. Mathematically, it differs from the Wiener process by the presence of a decay term in the drift coefficient, which acts as a restoring force that pulls the particle back toward its starting point. For a particle starting at the origin ($X_0 = 0$), the OU process is defined by the stochastic differential equation,

$$\mathrm{d}X_t = (\mu - \beta X_t)\mathrm{d}t + \sigma \mathrm{d}W_t. \quad [9]$$

In this equation, μ is the external component of drift, which in decision-making models depends on the stimulus, $-\beta X_t$ is the restoring force, and σ^2 is the diffusion coefficient. When $\beta = 0$, the process becomes the Wiener diffusion process of Ratcliff's model (with $\mu \equiv \xi$ and $\sigma \equiv s$). Busemeyer and Townsend (1993) interpreted the OU decay term in their model as representing avoidance in a system of approach-avoid dynamics.

Most applications of diffusion models before Busemeyer and Townsend (1993) had been to brief two-choice decisions based on a single, 'one shot' cognitive process, for which RTs do not average much more than a second. They proposed that diffusion models could also be applied to more complex tasks, in which decisions are made after a period of deliberation. They showed their OU model could provide an account of otherwise puzzling findings in the judgment and decision-making literature, such as preference reversals, which are difficult to explain using traditional algebraic models (Roe et al., 2001).

Other investigators have proposed OU models in which the decay term represents a bounded evidence accumulation process. Smith (1995) proposed a model of simple RT with time-varying drift, $\mu(t) - \beta x$, in which the decision process is driven by sustained and transient visual channels. Usher and McClelland (2001) proposed a neurally inspired model of choice RT, the *leaky competing accumulator model* (LCA), based on a pair of coupled OU processes. Their model combined the properties of earlier accumulator models, such as that of Vickers (1970) – in which evidence for competing responses is accumulated in parallel by racing evidence totals – and diffusion process models, in which the accumulation process is diffusive. Denoting the evidence totals by X_1 and X_2 (and suppressing the dependence on the time variable, t), the growth equations in the LCA model are

$$\mathrm{d}X_i = (\mu_i - \beta X_i - kX_j)\mathrm{d}t + \sigma \mathrm{d}W_i, \quad i, j \in \{1, 2\}, \quad i \neq j. \quad [10]$$

In these equations, k is a coupling coefficient that represents the amount of mutual inhibition between the accumulating totals X_1 and X_2, and W_1 and W_2 are independent Brownian

motion processes. The relative optimality properties of the model were analyzed by Bogacz et al. (2006).

Diffusion Models and Empirical Data

Scaling and Distribution Shape

The two dependent variables, RT and accuracy, have different scale properties. RT has a minimum value, and its variance increases as RT increases. Accuracy is bounded on the range 0.5–1.0, and its variance decreases as it approaches 1.0. Diffusion models account for these scale properties automatically as a result of the geometry of the diffusion process. When mean drift rate is high, the probability of a correct response is near 1.0, and decision processes approach the correct boundary with little spread in arrival times. When mean drift rate is nearer zero, variability leads some processes to hit one boundary, other processes to hit the other boundary, and accuracy nears 0.5; the arrival times at boundaries are long and highly variable. In addition to these scale properties, the geometry of the diffusion process also gives RT distributions that are skewed to the right; as mean RT increases, due to a reduction in drift rate, the fastest responses slow a little and the slowest responses slow a lot.

Speed Versus Accuracy

People can manipulate their speed performance relative to their accuracy performance. If they are instructed in some blocks of an experiment to respond as quickly as possible, and in other blocks to respond as accurately as possible, mean RTs can vary between the two kinds of blocks by as much as 500 ms and mean accuracy can vary by 10% (Ratcliff and Rouder, 1998). Ratcliff's diffusion model can account for these differences with only the boundary separation parameter: moving the boundaries close together produces fast responses for which variability in drift can cause large numbers of errors; moving the boundaries further apart produces slower responses that are more likely to be accurate.

Error Response Times

Historically, comparisons of sequential-sampling models focused on their ability to predict empirical patterns of mean RTs for correct responses and errors. A problem with early random walk models was that they predicted that mean RTs for correct responses and errors would be the same. Specifically, the models predicted that $M(T_a|s_a) = M(T_a|s_b)$ and $M(T_b|s_b) = M(T_b|s_a)$, where $M(T_i|s_j)$ denotes the mean time to make response R_i when stimulus s_j is presented. This prediction is made by both SPRT random walks and Gaussian random walks in which the drift rates for the stimuli s_a and s_b are of equal magnitude and opposite sign: μ and $-\mu$, respectively (Luce, 1986; Townsend and Ashby, 1983).

A claimed advantage of the class of accumulator models (the right branch of **Figure 1**), which includes the recruitment model (LaBerge, 1962), the Poisson counter model (Townsend and Ashby, 1983), and the Vickers accumulator model (Vickers, 1970), is they predict that mean RTs for error responses will be slower than mean RTs for correct responses. But this represents only a partial solution to the problem of RT ordering, as errors can be faster or slower than correct responses depending on stimulus discriminability and instructions (Luce, 1986). Laming (1968) showed that variability in the starting point of a SPRT random walk allowed the model to predict fast errors, but this too represented only a partial solution.

One solution to the RT ordering problem was proposed in Link and Heath's (1975) relative judgment theory, which allows the distribution of evidence states, Z_j, in eqn [2] to be non-Gaussian. They showed that the ordering of mean RTs for correct responses and errors depends on the relative sizes of the steps taken by the walk toward the correct and error boundaries, which is characterized mathematically by asymmetry in the moment generating function of the evidence states. By allowing the asymmetry to vary freely, the model can predict either fast or slow errors. Although this yielded a formal solution to the problem of mean RT ordering, the theory did not provide an account of why the evidence distribution should vary with conditions that produce changes in ordering, such as instructions to respond rapidly or slowly.

Ratcliff's diffusion model, with trial-to-trial variability in drift rate and starting point, provides an alternative solution to the ordering problem. As a Gaussian process, it predicts equal mean times for correct responses and errors when there is no trial-to-trial variability. When there is variability in both drift and starting point, it can predict fast errors and slow errors, and the crossover pattern found in some experiments in which errors are faster in some conditions and slower in others (Ratcliff and Smith, 2004). As well as predicting the ordering of mean RTs, it also predicts the ordering of correct and error RT distributions. It therefore gives a complete account of the data from simple two-choice decision experiments. Unlike moment-generating function asymmetry, the sources of trial-to-trial variability in the model have clear psychological interpretations.

Quantile Probability Plot of RT Distributions

An experimental task in which the difficulty of the stimulus discrimination is varied yields a family of RT distribution pairs and choice probabilities. Each stimulus condition yields a distribution of correct responses and a distribution of errors, and the probability of a correct response. These data, which impose strong constraints on models of the decision process, can be represented in the form of a quantile probability plot, as shown in **Figure 3**. The RT distributions are summarized by their .1, .3, .5, .7, and .9 quantiles. The .1 quantile summarizes the leading edge of the distribution; the .5 quantile summarizes the 'typical' (median) response; and the .9 quantile summarizes the distribution's tail. For a given experimental condition, i, the quantiles of the distribution of RTs for correct responses are plotted against the probability of a correct response, q_i, and the quantiles of the distribution of RTs for errors are plotted against the probability of an error response ($1-q_i$). The distributions on the right of the .5 point on the x-axis are the distributions of correct responses, and the distributions on the left are the distributions of errors.

The main features of performance are shown on this plot. The spacing of the RT quantiles on the y-axis shows the unimodal, positively skewed form that is typical of RTs in

Figure 3 Quantile probability plot. Quantiles of the RT distributions are plotted on the *y*-axis against choice probabilities on the *x*-axis. The experimental task was a motion discrimination task in which discriminability was manipulated by varying the coherence of the motion in six steps. The *x*'s are the experimental data; the *o*'s connected by continuous lines are the fitted values of the Ratcliff diffusion model. Source: Ratcliff, R., McKoon, G., 2008. simple cognitive tasks. The mean and standard deviation of the RT distributions increase, roughly in proportion to one another (Wagenmakers and Brown, 2007), as the discriminability of the stimulus is reduced. Most of the change in the RT distribution with changes in stimulus discriminability occurs in the tail; there is little change in the leading edge. In the data set shown, error RTs are typically slower than correct responses, which appears as an asymmetry of the plot across its vertical midline. **Figure 3** also shows fits of the Ratcliff diffusion model to the RT distributions and choice probabilities. The figure shows that the model captures the shapes of the RT distributions for correct responses and errors and their relationship with the proportions of correct and error responses.

Comparison of Diffusion and Accumulator Models

Ratcliff and Smith (2004) compared the performance of diffusion models, accumulator models, and models combining the attributes of both classes, in which evidence for competing responses accumulates in separate totals that are modeled as diffusion process. One such model was the LCA model (eqn [10]); the other, the *dual diffusion model*, assumed a pair of independent parallel diffusion processes. This model is like the LCA model but omits the mutual inhibition term, $-kX_j$, of eqn [10].

Ratcliff and Smith found that model architecture – whether a model assumed one evidence total or two – was less important than the process used to model evidence accumulation. Models with diffusive evidence accumulation, in either a single evidence total or two racing totals, were able to account for the main features of the experimental data, whereas the accumulator models were not. Accumulator models predict RT distributions that become less skewed and more symmetrical with increases in the mean and variance of RT, which is not what is found experimentally (e.g., **Figure 3**). The successful models assume that accumulating evidence can both increase and decrease, whereas in the unsuccessful models it only increases. Models with diffusive accumulation predict the shapes of RT distributions that are found empirically, whereas models with other kinds of accumulation process do not.

For the diffusion and hybrid accumulator–diffusion models, neither decay nor mutual inhibition between evidence totals was needed to account for empirical data – although these features are often thought to confer biological plausibility. With small values of decay, β, the OU model (eqn [9]) was indistinguishable from the Ratcliff diffusion model. With large values of decay, it predicted RT distributions that were more skewed than those found experimentally. The LCA model, which assumes mutual inhibition between evidence totals, and the dual diffusion model, which does not, gave similarly good accounts of the data. Mutual inhibition appears to be needed in models in which stimulus inputs only produce increases in evidence totals; in such models, mutual inhibition can provide the fluctuations in evidence needed to correctly predict RT distributions (e.g., Purcell et al., 2012).

Neural Studies of Diffusion Making

Recently, there has been considerable interest in neural analogs of diffusion processes. This has been stimulated by the emerging subdiscipline of neuroeconomics, which focuses on the computation of value, reward, and uncertainty in the brain (Glimcher et al., 2009), and by single-cell recordings from awake behaving monkeys performing eye-movement analogs of human-speeded decision tasks (Hanes and Schall, 1996; Roitman and Shadlen, 2002). These studies have reported patterns of firing rates in decision-related brain structures that appear to be neural correlates of the accumulation process hypothesized in the psychological models (Ratcliff and Smith, 2004). Cells in brain structures like the frontal eye fields, lateral interparietal area, and superior colliculus, which respond selectively to the presence of one of the decision alternatives in their receptive fields, show a progressive increase in firing rates to a constant level that is time locked to the production of a response. This characteristic pattern of firing rates appears to be the neural signature of the process of accumulating evidence to a criterion.

In the past decade, there has been a proliferation of research investigating the connection between the psychological processes of evidence accumulation and the neural processes of decision making. Ratcliff et al. (2007) showed that the parameters of a dual-diffusion model estimated from the RT distributions and choice probabilities of monkeys performing an eye-movement decision task correctly predicted the time course and relative firing rates in build-up cells in the superior colliculus in the period preceding the response. Ratcliff et al. (2009) identified a late

component of the human electroencephalogram (EEG) that indexes decision making and showed that trial-to-trial variations in the amplitude of this component predicted estimates of drift rates in a diffusion model fitted to the RT distributions and accuracy data. Mulder et al. (2012) linked estimates of bias (starting point, z) in a diffusion process to activity in frontoparietal brain areas involved in the processing of probabilities and rewards.

Smith (2010) investigated the Poisson *shot noise process* (Gardiner, 2004) as an idealized model of neural information coding. He showed that when evidence states are described by the difference of two shot-noise processes, the resulting accumulation process approximates an integrated OU process, or *OU displacement process*. This process, which is the time integral of the OU velocity process in eqn [9], has similar properties to the Wiener diffusion process in Ratcliff's model and, consequently, makes similar RT distribution and accuracy predictions. It thus provides a theoretical account of how diffusive information at a behavioral level can arise from the statistical coding of stimuli in the underlying neural population.

Conclusions

Many researchers have contributed to the development of sequential-sampling models since they were introduced into psychology in the 1960s, and many different models have been proposed of how evidence is accumulated to make a decision. Models that represent evidence accumulation as a diffusion process have been particularly successful in accounting for performance in a wide variety of speeded decision tasks. Neuroscientists have begun to study the brain processes involved in decision making and have reported patterns of activity that appear to be correlates of the psychological processes of evidence accumulation hypothesized in the models. The models thus appear to have the potential to help us understand the theoretical link between behavior and its neural underpinnings.

Diffusion: Anthropological Aspects

Abstract

To study phenomena like communication, migration, epidemics, and trade is to study diffusion. In social and cultural anthropology, the systematic study of cultural diffusion emerged in contradistinction to speculations about humanity's cultural evolution from primitive origins to a state of civilization. The research of diffusion has been a constant in anthropology ever since, although the designations for the topics of this research have shifted. This article presents key topics in the anthropological study of cultural diffusion, including acculturation, world system, globalization, and the social life of things.

Diffusion Studies and Evolutionism

In a social-scientific sense, diffusion is the spreading in space and time of animate and inanimate objects, including human beings, and material and immaterial forms. To study phenomena like communication, migration, epidemics, and trade is to study diffusion. The question diffusion studies ask is: How did this (or he or she) get from there to here, from then to now? The focus in diffusion studies can be either on that which is diffused, e.g., in terms of isomorphism, relatedness, frequency, and comparison, or on the process of diffusion itself, e.g., in terms of contacts, paths, networks, and patterns. In social and cultural anthropology, the study of diffusion, on the whole, has gradually moved from a focus on that which is diffused to the process of diffusion itself. According to the historian of anthropology, George Stocking (1995: 180), diffusion is "one of the ur-forms of anthropological speculation in the Western-European intellectual tradition." Historically, however, the systematic concern with cultural diffusion in social and cultural anthropology emerged as an explicitly antispeculative project. Initially, it developed from the close study of artifacts that had been collected by Europeans on their journeys to different parts of the world. In private and public collections, such objects had been organized according to the assumption that they represented different stages in a process of orthogenetic human evolution. This idea, which had been common since the Enlightenment, is succinctly encapsulated in the title of one of Lewis Henry Morgan's (1818–81) works: *Ancient Society, or Researches in the Lines of Human Progress from Savagery Through Barbarism to Civilization* (1877). One of German anthropology's pioneers, Adolf Bastian (1826–1905), rejected the method of evolutionary deduction in ethnography, according to which individual ethnographic objects and traits were placed in a singular sequence of cultural achievement. He insisted on induction as the only scientifically valid method: it was possible to infer from the particular instances of artifacts and ethnographic data to the general level of 'folk ideas,' i.e., the environment-specific configurations of humanity's commonly held 'elementary ideas' (the latter concept inspired Carl Jung to formulate his idea of 'archetypes').

Diffusionism

Bastian was in turn criticized for being unscientific by another German anthropologist, Friedrich Ratzel (1844–04), who objected to his explaining cultural differences in terms of psychological maturity. Bastian believed that the technical sophistication of objects reflected the level of psychological maturity a cultural group had reached. Ratzel thought that charting the paths of cultural diffusion ought to come before causal explanations: "The first question here is not: Why?, but Where? And the second question after that is: Whence?" (Ratzel, 1897: 270). Bastian and Ratzel stood on opposite sides not just when it came to anthropological theory and method but with regard to politics as well (see Smith, 1978). Bastian advocated a liberal agenda of German industrialization and international free trade; Ratzel believed in protecting German agriculture through tariffs and national expansion. Bastian (1893) publicly opposed the acquisition of new German colonies; Ratzel (1884) was convinced that colonization through Germans settling overseas could solve social problems at home and lend greatness to the newly united German Reich. Ratzel's political stance fused with his theoretical program, which rightfully can be defined as the beginning of diffusionism in anthropology. Thus, just as in British and American anthropology, the politics of colonization and colonialism, as well as modernization, were intertwined with theory in German anthropology.

Since Ratzel believed that the principal mechanism of diffusion was migration, he arrived at the conclusion that "migration theory is the fundamental theory of world history" (Ratzel, 1882: 464). Fritz Graebner (1877–34), whose diffusionist *Methode der Ethnologie* (1911) was the period's most influential theoretical and methodological work of German anthropology, wrote that Ratzel's focus on migration and cultural borrowing put in question assumptions about organically grown and integrated local cultures and opened up the possibility that whatever one finds in any one location is a cultural hybrid ('Kulturmischung' in German; Graebner, 1911: 93). In 1904, Graebner and his colleague Bernhard Ankermann (1859–43) outlined their self-consciously formulated diffusionist project at the meeting of the Berliner Gesellschaft für Anthropologie, Ethnologie und Urgeschichte. Two years later, Father Wilhelm Schmidt in Vienna founded the foremost diffusionist journal *Anthropos*. At University College, London, Grafton Elliot Smith and his disciple William Perry tried to prove that culture had diffused to the rest of the

world from a single center of innovation, namely, ancient Egypt:

> … towards the close of the period of the New Empire, or perhaps even a little later, a great many of the most distinctive practices of Egyptian civilization suddenly appeared in more distant part of the coast-lines of Africa, Europe, and Asia and also in course of time in Oceania and America (Smith, 1916: 3).

As chief agents of diffusion, Smith and Perry identified the Phoenicians. W.H.R. Rivers, who worked at Cambridge, UK, and who had been a member of the Torres Strait Expedition, emerged as the most influential British anthropologist in the first two decades of the twentieth century. After conducting\fieldwork among the Todas of southern India in 1902, Rivers turned to 'ethnological analysis,' i.e., diffusionism, in which he combined influences from Elliott Smith, Graebner, and Sigmund Freud (cf. Rivers, 1911).

From Diffusionism to Acculturation Studies

As mentioned, a significant source of diffusionism was the political question of colonialism. Another source was the scholarly issue of historiography. Diffusionism is interspersed with implicit (and a few explicit) references to Leopold von Ranke's (1795–86) historicism, which emphasizes that one needs to move as closely as possible to the sources of knowledge (empiricism) and that one must understand the past in its own terms (relativism). This legacy migrated from Germany to the United States and shaped American cultural anthropology.

The German anthropologist Franz Boas (1858–42), who, for a while, had been a member of Bastian's staff at the ethnographic museum in Berlin and who was well acquainted with the debates in German anthropology, settled in the United States in the late 1880s. In the Pacific Northwest, he went on to collect specimens, information in the native language about these specimens, and grammatical information necessary for the interpretation of this information. His ambition was to reconstruct a cultural history of the nonliterate indigenous people he studied. Boas developed his diffusionary analyses most systematically in the field of linguistics. At the same time, Boas was highly critical of certain types of diffusionism. In particular, he rejected the idea that cultural traits persist over time and that they were distributed from a single center through man's migration across continents (see Boas, 1920). Cultural traits do not remain unchanged, contended Boas; all cultures have a history, which includes both acculturation and innovation or adaptation.

In the face of a methodological shift in anthropology, with direct observation during extended times of fieldwork replacing both the study of museum specimens and survey studies with the help of questionnaires, the reconstructive work of diffusionism fell into disrepute in much of anthropology. Cultural interaction, however, continued to be a core issue and was now studied under the headings of culture contact, culture change, and acculturation. Acculturation, the key concept in this context, was defined as follows: "Acculturation comprehends those phenomena which result when groups of individuals having different cultures come into continuous first-hand contact, with subsequent changes in the original cultural patterns of either or both groups" (Redfield et al., 1936: 149). The image of the World War I as a conflict in which the products of industrialization – machines, chemicals, automatic weapons, etc. – mangled human bodies cast a shadow over the belief in evolutionary progress. Following World War I, culture contact had become a matter of self-conscious reflection among European intellectuals:

> The great world-shattering changes of the past decade, the War, the Russian Revolution, the Treaty of Versailles and the consequences of these events, have led men to question for the first time many of the previously unchallenged assumptions implicit in their own civilization, whilst it has prompted them to regard with real concern and a desire to understand civilizations unlike their own (Pitt-Rivers, 1927: xii).

Some acculturation studies, like those of Pitt-Rivers, were explicitly directed at the types of political domination that in so many instances produced culture change during colonialism. Thus, Richard Thurnwald (1932: 568f) distinguished between two kinds of acculturation through colonial relations: on the one hand, the biological and cultural mixing between men and women, and on the other, formal relations of tutelage. In the one instance, acculturation was a matter of intimate relations, of primary socialization into local traditions in the form of care, which attributed to women as 'principal caretakers,' the role of keepers of tradition. In the other case, social relations consisted of formal education or secondary socialization through 'channels by which the new and foreign flows,' such as 'missions, schools, governmental ordinances, control of courts, etc.' Thurnwald's analysis is typical of a move in diffusion studies from a focus on that which is diffused to the process of diffusion itself. In his model, cultural diffusion in the context of intimate relations provides cultural continuity; diffusion in vertically structured formal settings of colonial relations introduces foreignness. The latter circumstance has been analyzed, e.g., by Frantz Fanon in terms of the colonized self absorbing the image of inferiority, which the colonizer projects onto her or him (see Fanon, 1952).

Decades later the difference between types of cultural transmission was discussed in terms of 'antagonistic acculturation.' American anthropologists began to investigate why some cultural groups resisted formal colonial tutelage and the 'modernization' it was to bring, and others did not. The cause was sought in the rigidity and closeness of some societies versus the adaptability and openness of others. One suggestion was that it was possible to distinguish 'hard-shelled, vertebrate' from 'soft-shelled, invertebrate' cultural systems (Social Science Research Council Summer Seminar, 1954: 978). For instance, two Native American groups were studied with regard to how they received tribal members who returned as World War II veterans (Adair and Vogt, 1949). One group was described as engaging in 'antagonistic acculturation,' that is, to resist culture change. The other group was described as 'receptive,' 'flexible,' and 'intensely curious about the outside world' (Adair and Vogt, 1949: 558–60). The latter seemed to be

what Margaret Mead (1938) once called 'an importing culture.' These characteristics were attributed to different types of social organization, ritual systems, and collective dispositions. The attention to relations of domination that had been present in studies like those of Pitt-Rivers and Thurnwald gave way to a perspective that, at least implicitly, valued cultures that were open and adaptive to modernization.

Critical Studies in Diffusion

Subsequently, mainstream studies of culture change were less modernization friendly. Not simply because their authors promoted the preservation of indigenous cultures, as generations of anthropologists had done before, but because they placed colonial relationships in a wider, global system of capitalism. Since the late 1960s, a critical anthropology of neo-colonialism and global capitalism developed under the influence of Andre Gunder Frank's (1969) thesis that underdevelopment was not a result of traditionalism, but of colonial exploitation (the development of underdevelopment), and of Immanuel Wallerstein's (1974) synthetic work about the dynamics of European expansion and the center–periphery structure of the capitalist world-system. This type of anthropology tended to treat cultural diffusion as a secondary effect of worldwide economic structures and relations. It did not grant an independent cultural logic to the global periphery, holding the periphery to be open to radical change initiated by the center. Marshall Sahlins (1985: viii) called this 'a confusion between an open system and a lack of system.'

In response to models of cultural imperialism that treated the so-called periphery as susceptible to anything arriving from the global centers, anthropologists began describing local responses to colonial and capitalist diffusion. Ethnographers had for some time provided examples of culturally creative responses to capitalism's local encroachments in different parts of the world (see Nash, 1981 for a review of this rich ethnographic genre). Classic examples include Eric Wolf's (1958) research of syncretism (i.e., the synthesis of indigenous and diffused cultural elements) in the case of the Virgin of Guadalupe; the ethnographic documentary film, *Trobriand Cricket: An Ingenious Response to Colonialism* (1973) by Gary Kildea and Jerry Leach; and Michael Taussig's ethnography, *The Devil and Commodity Fetishism in South America* (1980). Syncretism, hybridity, and creolization were key concepts in this anthropological genre.

Beginning in the 1980s, a number of anthropologists turned their attention to the global aspects of cultural diffusion. At issue was the question whether what was described as a process of cultural globalization would lead to cultural homogenization (coca-colonization) or if, on the contrary, and in the spirit of the just mentioned concern with local responses to colonialism and global capitalism, globalization actually created new forms of cultural diversity (see, e.g., Hannerz, 1987).

The Social Life of Things

Of some interest in this context is Arjun Appadurai's anthology on *The Social Life of Things: Commodities in Cultural Perspective* (1986), in which a number of scholars revisit the subject of material diffusion, only that they now follow artifacts and commodities through the networks of diffusion and investigate how the cultural meanings attached to the objects change in the process. What becomes apparent in contributions like that of Brian Spooner (1986) is that the path of commodities through international, vertically structured trade networks can involve complex flows of values and meanings both upstream and downstream.

Appadurai's approach – treating objects as if they are animate (as if they have social lives and cultural biographies) – is reminiscent of current preoccupations with material–semiotic relations in the anthropological study of science and technology, e.g., as conducted and elaborated by the French anthropologist Bruno Latour. Latour, in turn, acknowledges his debt to the French sociologist Gabriel Tarde (1843–04), who posited that the laws of diffusion (or, as he called it, 'imitation') are fundamental to all processes in both natural and social life (see Tarde, 1890). Compared with Appadurai's empirically informed method of following the object in space and time and registering how it, during its journey, is charged with values and meanings, Tarde's laws are metaphysical and in need of translation to be applied in social-scientific research.

In some neighboring disciplines, the idea to trace the diffusion of particular phenomena has been pursued to such an extent, and with such systematic rigor, that it has given rise to subdisciplines and schools of thought. In history, for example, one finds a British and a German version of semantic history, both of which record and analyze the changing meanings of social and political keywords over time. The Cambridge School of History is associated, first and foremost, with the names of J.G.A. Pocock and Quentin Skinner and their research on political languages for the sake of uncovering linguistic universes. In Germany, 'Begriffsgeschichte' (the history of concepts) was pursued as a distinct intellectual project by a group of historians, from which Reinhart Koselleck emerged as the most prominent figure. His research demonstrates that there was a consequential semantic shift in Europe's social and political language in a period stretching approximately from 1750 to 1850.

For the Cambridge School and Begriffsgeschichte, the diffusion of social and political key concepts and the semantic changes they underwent is inferred from the close investigation of historical sources. In sociology, institutionalism – both old and new – also employs induction from historical materials to formulate theories about big structures and large processes. The founder of new institutionalism, John W. Meyer, has been interested in the diffusion of instrumental rationality and its institutions, as well as in the irrational outcomes this diffusion may have (see Meyer and Rowan, 1977, for an early formulation of new institutionalism). In a similar vein, the French anthropologist Loïc Wacquant follows the diffusion of ideological matrixes and the accompanying confusion about the origins and consequences of such matrixes (see, e.g., Wacquant, 1999). In economics, the study of commodity and value chains has become a field of inquiry in its own right (see, e.g., Gereffi and Korzeniewicz, 1994) that has moved from a more descriptive, historical to a more prescriptive, managerial approach.

As a research agenda and method, following objects, concepts, institutions, normative orders, people, etc. along paths of diffusion and migration is far from exhausted. Anthropologists ready to conduct multisite fieldwork and to study primary source materials are in a privileged position to engage in this kind of scholarship with the necessary empirical precision.

Diffusion: Geographical Aspects

Lawrence A Brown[†], The Ohio State University, Columbus, OH, USA

Abstract

Geographic diffusion involves the propagation of innovation or other phenomena, focusing on spread from place to place, leading to maps that differ from one time to another. Innovations have received most attention – a new product, idea, technology, organizational structure, or way of doing things – where new means new to a particular place through adoption. Geographical diffusion, a long research tradition, has changed focus and content from epoch to epoch in social science, ranging from cultural formation to economic phenomena and to positivist social science. Prime among the foci are the following: (1) The Cultural Geography Tradition – in the early middle 1900s, the concern was cultural formation; (2) The Hagerstrand Tradition – beginning in the 1970s, the focus turned to structural influences on diffusion; (3) The Market and Infrastructure Perspective – emphasis shifted to the spread of technological and organizational innovation in economic activity; (4) Technological Diffusion – focus is mainly on Third World development; as well as (5) Development as a Diffusion Process. At the century's end, innovation itself became a major focus wherein diffusion within such endeavors is a primary element, that is (6) Diffusion and Innovation. Geographical diffusion represents one approach in a multidisciplinary suite that includes contributions from anthropology, communications, economics, marketing, political science, psychology, sociology. Accordingly, constructs of geographic diffusion may also occur in research by others, for example, interpersonal interactions, media effects, utility maximization, and marketing strategies. In these instances, the critical contributions of a spatial perspective to understanding diffusion dynamics, and innovation itself, are apparent.

Introduction

From a geographic perspective, diffusion involves the propagation of a phenomenon in a manner that it spreads from place to place; incorporates basic geographic elements of distance, direction, and spatial variation; and leads to maps that differ from one time to another. Most commonly the phenomenon is an innovation – a new product, new idea, new technology, new organizational structure, or new way of doing things – where 'new' means new to a particular place by way of adoption. Hence, diffusion phenomena cover a wide range that includes transportation modes such as the automobile; farming techniques; family planning; credit cards; broadcast and cable television; shopping centers; production practices, such as the assembly line or just-in-time inventorying; political movements; cultural practices; frontier development; modernization in Third World settings; epidemics; urban ghettoes; and urban areas themselves. The enormous range of phenomena studied under the diffusion rubric is further indicated by Brown (1981), Morrill et al. (1988), and Rogers (2003).

While geographers have studied diffusion since early in the twentieth century, the focus has shifted over time, often with marked departures from prevailing norms. Consequently, early diffusion studies by cultural geographers may be hardly recognizable as similar in genre to recent studies, focusing on entrepreneurial agents in diffusing products and diffusion itself as a major factor in innovation.

The Cultural Geography Tradition

Within geography, diffusion studies originated through a concern with culture in terms of

> the changing distribution of 'culture areas' … identify[ing] environmental features characteristic of a given culture and … discover[ing] what role human action … has played in creating and maintaining given geographic features.
>
> Wagner and Mikesell, 1962: p. 1

This tradition dominated pre–World War II scholarship and focused on change in indigenous cultures, often centuries ago. Culture and the human or cultural landscape are the primary focus, and diffusion studies are relevant in clarifying questions concerning culture origins, the spatial configuration of culture areas, and culture-related or culture-influenced features on the Earth's surface. Carl Sauer was the central figure in this approach, which tended to be closely aligned with and complementary to some concerns of anthropology (Mikesell, 1978).

Within this framework, many studies aim to assess the relative importance of diffusion vs simultaneous invention in development of cultural landscapes. They employ an empirical, inductive approach with emphasis on landscape development in prehistory and/or over considerable periods of time. Often investigation considers a single phenomenon, seen as a culture trait, and explains its observed spatial distribution as the outcome of processes unfolding over space and time. A typical procedure is to examine a phenomenon's spatial distribution at different times or its frequency of occurrence in different locations at a single time. Inferences are drawn regarding origins (or cultural hearths), means, and routes of dispersal of both the observed phenomenon (culture trait) and the ideas, technology, or culture for which it is a surrogate. Attention is also given to cultural and environmental conditions necessary for adoption of particular phenomena and to macroscale, big-picture phenomena such as the domestication of plants and animals, their origins, routes of dispersal, and destinations (Sauer, 1952; Wagner and Mikesell, 1962).

[†] Deceased.

In stressing the role of diffusion in development of the human landscape, many cultural geography studies proceed further to consider indirect effects of the culture trait innovation on the physical and cultural environment. A basic notion is that the diffusing item is both a stimulus to new innovation and itself subject to modification as it spreads. The relation between diffusion, the item being diffused, and the human landscape is therefore complex and subject to continual change.

The Hagerstrand Tradition

Sauer's counterpart in later diffusion research is Torsten Hagerstrand who, in the early 1950s, initiated a shift toward the generative processes underlying diffusion and modern-day products and practices. As this focus is consistent with Sauer's conceptualization, why was process less prominent in earlier research? One reason may be that identification of processes controlling locational change is less feasible in the sparsely documented situations studied by cultural geographers. Second, Hagerstrand's main impact was on researchers in economic and urban geography who were primarily concerned with location and locational processes rather than landscape. Illustrative is Haggett's (1965: pp. 10–13) classification of research under the Sauer school as landscapist or ecologist and research under the Hagerstrand school as locationalist.

Hagerstrand's research (1952, 1967) focuses on diffusion of contemporary innovations such as the automobile and bovine tuberculosis control. His first study, *The Propagation of Innovation Waves* (1952), continues the cultural geography tradition by its use of an inductive approach and concern with diffusion pattern rather than process. At a somewhat later date (1953), however, Hagerstrand observed that…

> spatial order in the adoption of innovations is … so striking that it is tempting … to create theoretical models which simulate the process and make predictions achievable.
>
> Berry and Marble, 1968: p. 370

This statement indicates a change from description and inductive generalization to a more deductive approach focusing on generative processes. The work marking this shift is Hagerstrand's PhD dissertation of 1953, subsequently translated into English as *Innovation Diffusion as a Spatial Process* (1967). Hagerstrand made three contributions that were transformative at the time, and continue to play a role in diffusion research.

Empirical Regularities in Diffusion

Three regularities characterize diffusion. Over time, a graph of the cumulative level of adoption is expected to approximate an S-shape that rises with the passage of time. In an urban system, diffusion is expected to proceed from larger to smaller centers, regularity termed the hierarchy effect. Within the hinterland of an urban center, diffusion is expected to proceed in a wavelike fashion outward from the urban center, first hitting nearby rather than farther-away locations, and a similar pattern is expected in diffusion among rural populations. This regularity is termed the neighborhood or contagion effect.

Hagerstrand (1952) also provides a framework that connects these regularities. For diffusion in an urban system, this posits three phases: a primary stage, during which initial diffusion centers are established; a diffusion stage, during which neighborhood-type diffusion occurs in areas near diffusion centers and secondary diffusion centers are established in lower order urban places; and a condensing or saturation stage, during which filling in occurs and diffusion eventually ceases.

This framework thus illustrates the complementarity of hierarchy and neighborhood effects and their temporal positioning within diffusion. Also, if locales of adopters were tabulated, higher order urban places characterize the left tail of the S-curve of adoption; lower order urban places characterize the middle, sharply rising portion of the S-curve, along with rural hinterlands in proximity to urban centers; and remote rural hinterlands characterize the S-curve's right tail.

Hagerstrand's Conceptualization of the Diffusion Process

Hagerstrand's conceptualization of innovation diffusion across the landscape holds that adoption is primarily the outcome of a learning or communications process. Factors related to the effective flow of information are most critical and, therefore, a fundamental step in examining diffusion is identifying spatial characteristics of information flows and resistance to adoption.

In Hagerstrand's conceptualization, information originates from the mass media or past adopters. The destination of personal messages depends on a sender's network of social communications (interpersonal contacts), and configuration of this network reflects various social and terrestrial barriers that impede, divert, and/or channel communications. Particular attention is given to terrestrial barriers such as lakes, forests, difficult terrain, and geographical distance separating potential communicants.

The conceptualization further recognizes that resistance levels differ among individuals, and that higher levels of resistance require more information for adoption to occur. This leads to a dichotomy of resistance as either the result of values that are inconsistent with adoption (social resistance) or practicalities that make adoption difficult or impossible (economic resistance).

To address diffusion at different geographical scales, a hierarchy of networks of social communication is posited. One network might operate locally and another regionally. The first would control diffusion among farmers in a single locale, whereas diffusion at the central-place level of aggregation might utilize a regional network of persons in different urban areas that communicate with one another. Superimposition of these two levels provides a comprehensive picture of diffusion in the area represented.

In summary, Hagerstrand's conceptualization proposes transformation of a population from a low proportion of adopters to one with a high proportion, by means of information dissemination through media and interpersonal contact. Spatially, the principal mechanisms of transformation

are networks of social communication characterized by biases and distortions that, in turn, effect and are reflected in spatial patterns of innovation diffusion.

Hagerstrand's Methodological Framework

To implement his conceptualization, Hagerstrand used Monte Carlo simulation. Adoption takes place after a specified number of messages are received, the specified number varying according to an individual's resistance to adoption, which is randomly assigned. Time is treated in discrete units of equal interval, and each past adopter sends a message in every time interval. The destination of messages depends on the probability of contact between tellers and potential receivers. This probability is a function of distance between them unless a water or forest barrier intervenes. A distance decay function is employed to compute the probability of interaction between each of 25 cells in a 5-by-5 cell grid and the center cell of that grid. The resulting grid of probabilities, termed the mean information field (MIF), is employed with a map gridded in a similar manner, but with more than 25 cells. The MIF is centered over a map cell containing an adopter of the innovation at time t; a random number is then drawn to determine which of the 25 surrounding map cells receives a message to adopt in time $t + 1$. If the message passes over a water or forest barrier, it is either nullified or a new random number is drawn, depending on the level of obstruction. This procedure is repeated for every adopter in every time interval. If a previous adopter receives a message, the message is lost; that is, it has no effect and is not repeated. If a message is received by a nonadopter who, owing to resistance level, requires more than one message before adoption, the message is stored until sufficient messages for adoption are accumulated.

This model mechanism is crude by today's standards of computational capability, but in the 1950s, it was highly innovative. Accordingly, Hagerstrand's diffusion model played an enormous role in geography's quantitative revolution of the 1960s and the 1970s, as both an example and a standard of excellence (Berry and Marble, 1968). This observation also applies to social science overall; the model is included, for example, in books such as Coleman's (1964) *Introduction to Mathematical Sociology*.

The Market and Infrastructure Perspective

Hagerstrand's formulation, and those of the many other social scientists studying diffusion from the 1950s onward, took an atomistic view of society as individuals with free will, any of whom could adopt an innovation. Thus, the onus of adoption was on individuals, who were classified on a scale ranging from innovator to laggard, with the social meaning each term implies (Rogers, 2003). This is termed the adoption perspective, focusing primarily on the demand side of innovation diffusion.

The market and infrastructure perspective focuses on supply or availability of the innovation (Brown, 1981). Rather than assuming that all have an equal opportunity to adopt, this is seen as purposely and egregiously unequal, so that adoption represents a choice within a constraint set; government, nonprofit, and entrepreneurial institutions establish these constraints; and attention is given to the process by which innovations and conditions for adoption are made available to individuals, households, or firms. Hence, focus shifts from the individual to the structure within which individuals operate, paralleling realignments in social science overall (Brown, 1999). Nevertheless, the market and infrastructure perspective is put forth as complementary, not contradictory, to the adoption perspective. Broad outlines of diffusion are shaped by where (and to whom) innovations are (made) available, but within those outlines, more detailed variation in diffusion patterns reflects adoption behavior.

Central elements of this perspective include the propagator of the innovation, the entity behind its diffusion; diffusion agencies (outlets) through which innovation is distributed to the population at large; and diffusion strategy, which is designed to encourage adoption and includes decisions on agency location, pricing, advertising, population segments targeted by promotional efforts, etc. Hence, locations and temporal sequencing of diffusion agencies determine where and when an innovation will be available and provide the general outline of the diffusion pattern. Diffusion strategy further defines the pattern by creating different levels of access depending on a potential adopter's economic, locational, demographic, and social characteristics. The final pattern occurs via adoption behavior, the last stage of the process. Interacting with these factors are infrastructures such as transportation and utility networks that are independent of the innovation's propagator and diffusion agencies, distinctly affect adoption, and upon installation may be seen as 'enabling' innovations.

Hence, the market and infrastructure perspective emphasizes the marketing aspects of diffusion, especially strategies for market penetration. Whether the propagator is profit or nonprofit motivated, broad acceptance is a common goal, and a strategy will be designed to accomplish this, that is, to best penetrate the market. This is also true whether propagation involves centralized decision making, decentralized decision making with a coordinating propagator, or decentralized decision making without a coordinating propagator, although such distinctions affect procedures by which diffusion occurs. Similarly, diffusion agencies may be represented by salespeople or agricultural extension agents but should be guided by marketing strategy and, accordingly, make selective decisions, regarding which potential adopters will be contacted or cultivated, and to what degree. Considering the role of infrastructure, broadcast television stations were needed before television sets diffused. Today, fiber-optic and satellite connectivity varies appreciably from place to place, affecting Internet availability. Enhanced accessibility through communication or transportation improvements increases the market areas of diffusion agencies and renders innovations more attainable to potential adopters. Also, for example, irrigation infrastructure is often critical to the success of high-yielding variety seeds in agriculture.

Finally, this framework calls into question hierarchy and neighborhood effect regularities, because relevant factors from a marketing perspective are often not arranged in that manner. The diffusion of cable television in Ohio, for example, occurred initially in small, more remote places where broadcast signals

were weak or nonexistent, because cable was a means of enhancing television sales by appliance stores.

Technological Diffusion

Agricultural technology has been a major concern of diffusion studies. Beginning in the 1930s, and accelerating thereafter, rural sociologists and agricultural economists, working through agricultural experiment stations and extension agents, carried out an enormous number of projects focused on farm innovations, such as hybrid corn, fertilizers, silage methods, high-yielding varieties, and the like (Rogers, 2003). Until recent industrial agriculture, the adopting unit was the farm household, thus joining this effort with diffusion research concerned with consumer innovations. Manufacturing firms that are well beyond household size also adopt technological innovations, as do service and retail firms. This has been studied extensively, but rarely joined with the body of diffusion research described previously.

Rather than emphasizing communications, studies of firm adoption give more attention to characteristics of the firm and innovation itself. Also significant is the fact that innovation replaces an older technology with a newer one, highlighting comparative costs, benefits, and risks as well as factors such as relative profitability, investment, sunk costs, and the like. In this regard, there is greater emphasis on innovation as a continuous process; one that might be tailor-made for a particular firm or firm setting, rather than as a singular, unchanging phenomenon; and one that involves a more intimate and ongoing relationship between the innovation's supplier and user. Issues such as competition among firms and relative factor prices, favoring one technology over another, also play a role.

As these factors indicate, economic perspectives are important to investigating the diffusion of technological innovations among firms (Brown, 1981). But spatial considerations enter in two ways. First, there has been a tendency to assume that larger firms in larger urban agglomerations are earlier adopters, giving rise to a self-reinforcing (cumulative and circular causation; Myrdal, 1957) hierarchy effect pattern of diffusion. In fact, earlier adopters are just as likely to be less than the largest in size, which may correlate with aggressiveness and innovativeness of management. There also may be a spatial order to innovative change, such that newer economic regions are favored, leading to regional rotation or spatial succession; Silicon Valley provides an example (Malecki, 1997). The second way spatial considerations come into play is that the study of technological innovation has become closely intertwined with regional development and regional economic change (Malecki, 1997). Hence, the questions may not be inherently geographic in terms of process, but very geographic in outcome. This is returned to in Section Diffusion and Innovation.

Development as a Diffusion Process

Seen as integral to economic development, diffusion of innovations in Third World settings has received much attention. Examples include improving agricultural production and living conditions, generating entrepreneurial activity and related employment, promoting family planning, and improving infrastructure. Research and policy have largely employed the adoption perspective, but examples of a market and infrastructure approach are also evident (Brown, 1981; Miller, 2009; Rogers, 2003).

More broadly, development itself has been treated as a diffusion process. One approach involves choosing an index of development, and tracing its spread across the landscape; this approach is similar methodologically to the culture trait studies of earlier diffusion research. Such indices include agricultural cooperatives, banking, communications (telegraph, telephone), educational facilities, electricity, employment patterns across economic sectors, medical services, police organizations, postal agencies, transportation modes (roads, rail), urbanization, and other artifacts of a market economy (Gould, 1976; Pedersen, 1975; Taaffe et al., 1963).

Frontier expansion has also been viewed in a diffusion framework (Hudson, 1969). Substantively, these studies focus on aspects such as capital generation and control; migration, travel, and trade interactions; the role of particular economic sectors such as banking and wholesaling; and transportation linkages (Meyer, 1980).

Finally, formal models of development have a distinct diffusion dimension. Modernization, dual economy, core periphery, growth center, and stages of growth frameworks put forth the notion that Third World settings are composed of traditional and modern elements, and that development consists of transforming traditional to modern. Dependency and related theories take a similar track, albeit one that differs in emphasis. These models divide Third World landscapes into dynamic, propulsive, modern cores, and traditional peripheries; development is represented by transformation and expansion of the modern; and this occurs through mechanisms such as information and capital flows, migration, human capital developments, and more generally, backwash, trickle-down, and imitation effects (Brown, 1991).

Diffusion and Innovation

Traditionally, diffusion studies have taken the innovation as given and research focuses on the mechanisms by which it penetrates society (Brown, 1981: pp. 3–12; Rogers, 2003: pp. 1–38). That this tradition continues is indicated by studies on the diffusion of the cellular telephone (Comer and Wikle, 2008), broadband availability, and internet usage (Brown, 2010: Whitacre, 2008), and the technologies of continuous steel casting, digital telephones, and shuttleless looms (Perkins and Neumayer, 2005).

This approach is consistent with the traditional 'linear model' of innovation wherein research (basic science, engineering) leads to discovery, production, and marketing as discrete activities. In recent years, however, research has concluded that a 'chain-linked' model is more appropriate, one wherein continual interaction and feedback take place among research, knowledge, invention, testing, design, redesign, potential markets, distribution, etc. (Caraça et al., 2009; Kline and Rosenberg, 1986; Sternberg, 2009). This framework also

applies to the seemingly more singular situation of innovation by users themselves (von Hippel, 2006). From this perspective, then, diffusion becomes an integral element of the innovation process.

Effective interaction among these various segments is enhanced through social and geographic proximity as represented by, for example, a shared knowledge base, language, cultural understanding, technical capacity, institutional practices, governmental policies, and distance itself (Lundvall, 1988). The result is Regional Innovation Systems, each with a distinct spatial expression in the form of innovative clusters, districts, and regions such as Baden-Württemberg, Boston's Route 128, and Silicon Valley (Asheim and Gertler, 2005; Cooke, 2001).

Further, regional innovation and production systems have themselves diffused over time (Castells and Hall, 1994; Malecki, 2010, 2011). Factors underlying this process include the ongoing upsurge in transportation, communication, and information technologies; formation of a global economy and multinational entities; enhanced abilities to tap distant skills and talents; and new organizational forms of production and management. Functionally, these range from highly creative nodes, ones whose innovativeness is more incremental, to sites where production is the sole concern.

Overall Observations

Diffusion comprises a long tradition of research in geography. From epoch to epoch in social science, it has changed focus and content. Geographical studies of diffusion also represent only one approach in that the topic is highly multidisciplinary including, at least, contributions from anthropology, communications, economics, marketing, political science, psychology, and sociology. Accordingly, concepts used by geographic studies of diffusion may be found in research by other disciplines, for example, interpersonal interactions, mass media effects, utility maximization, and marketing strategies. In all these instances, as well as in purely geographic studies, the critical contributions of a spatial perspective to understanding the dynamics of diffusion are apparent.

Abstract

The study of diffusion of behaviors has a long history in sociology. While the key elements of the processes were already well defined in traditional approaches, sophisticated models incorporating all of these ingredients necessitated modern advances in social network theories, models for social interactions, agent-based approaches and, importantly, the widespread use of simulation that could only be launched with remarkable advances in computer power. This article reviews the linkages between traditional and modern approaches to the study of diffusion processes.

Over the last 20 years or so there has been a remarkable swift progress in the formulation and analysis of diffusion processes in social sciences in general and sociology in particular. Past conceptualizations (Alter, 2001) have been superseded through a paradigmatic shift triggered by the introduction of sophisticated behavioral models from other disciplines, particularly economics, the rapid evolution of social network analysis, and the discovery and application of agent-based models (Palloni, 2001, 2003). The transition from the traditional to the new paradigm is, however, not yet complete and there is much ground to cover. Scarcely any of the progress made in the recent past would have been possible in the absence of significant advances in statistical inference, quantum leaps in computing power, and the development of new communication technologies and data gathering procedures.

Traditional Diffusion Theories

The most recent Encyclopedia entry on diffusion processes emphasized a traditional view that was mostly anchored in classic sociological theories and anthropology (Alter, 2001). At the time the entry was written there already was in place a solid sociological tradition, albeit youthful and underdeveloped, best represented by the classic and much cited work of Rogers (Rogers and Kincaid, 1980; Rogers, 1995). Rogers defines diffusion as "… a process by which an innovation is communicated through certain channels over time among the members of a social system …" (Rogers, 1995) or the diffusion effect as "… the cumulative increasing degree of influence upon an individual to adopt or reject an innovation, resulting from the activation of peer networks about an innovation in a social system ..." (Rogers, 1995). Rogers' main contribution at the time was to assemble in a coherent manner the stock of accumulated knowledge by the middle to the late 1970s and to articulate a conceptual framework that became the theoretical scaffold that supported numerous subsequent empirical studies.

The main object of study of standard diffusion theories is the process of adoption of innovations (behaviors, practices, beliefs, norms, etc.). By its very nature this process requires flows of information across actors and/or between a central source and groups of actors. Needless to say, the abandonment of practices, behaviors, beliefs, norms, etc., can also be studied as a diffusion process: in these cases what is adopted is a rejection behavior. Adoption of behaviors or practices is rarely a mechanical matter. Like conventional individual decision processes it involve actors with preferences and tastes, who face price and budget constraints, and who are set to maximize their utility in an environment characterized by uncertainty. Unlike conventional decision-making processes, diffusion involve actors whose calculus is significantly influenced by other group members' attitudes and behaviors (observed or expected) toward adoption.

It is not surprising that the most important application of diffusion studies involves the adoption of technological innovations. Some of the most influential early works include Ryan and Gross's (1943) analysis of the diffusion of hybrid corn, Hagerstrand's (1967) investigation of the diffusion of TB tests in Sweden, Coleman, et al.'s (1966) study of the adoption of tetracycline among Midwestern doctors, Katz and Lazarsfeld's (1955) celebrated formulation of the two-step flow of influence process, Rogers' contribution to the early empirical literature on farm innovations (Beal and Rogers, 1958), and Rogers and Kincaid work on contraceptive behavior (Rogers and Kincaid, 1980). The main goal of all these studies is to assess the effects of the mass media – a central source of diffusion – the degree of influence of individuals located at the top of the community hierarchy (agents of change), and the relative contribution of interpersonal interactions within the boundaries of the community where the innovation is spread. With the exception of the work by Hagerstrand and Ryan and Gross, these studies highlight the role of interpersonal relations and channels of influences as mechanisms fostering or impeding diffusion. They thus anticipate some of the most promising work on social influences in general and diffusion in particular that becomes solidly established and continues to develop from the early 1980s onward (Valente, 1995, 2010; Bandura, 1986; Moscovici, 1985; Marsden and Friedkin, 1993; Marsden, 1998; Erbring and Young, 1979; Granovetter, 1973, 1978).

Developing side by side with the sociological approach emerging in the works identified above, the bulk of empirical research in the area of diffusion rested on the formulation of models testable with aggregate information about behaviors,

such as the proportion of adopters, of susceptible to adopt, and of nonadopters. These formulations mimic contagion models for the spread of disease developed in epidemiology (Mahajan and Peterson, 1985; Anderson and May, 1992; Bailey, 1975). And while its appeal was rooted in their simplicity and low grade data-demands, their generalized use had the unfortunate consequence of portraying the social diffusion process as one where individuals are either passive carriers of information and innovations or passive 'susceptible' rather than actors who are decision makers, engaged in real social interactions, and whose calculus is influenced by other actors' choices and the effects of adoption on the group's morphology itself. Using highly stylized representations, these models eschewed explicit definition of the role of social networks, their social and spatial organization, and the relative positions of individuals in it. In the contagion-like models the richness of social interactions permeating the formulation of diffusion processes in traditional sociological approaches is either absent or concealed by invoking rigid and unrealistic assumptions. Thus, most of these models are deterministic, rest on strong assumptions about temporal and spatial homogeneity and rarely, if ever, explicitly introduce the role of relations between actors. While some of the stochastic variants of contagion models explicitly allow for social and spatial heterogeneity, they are mathematically intractable and, at least until recently, before the advent of powerful computers, led to only modest improvements of our knowledge about diffusion processes (Bartholomew, 1982; Bailey, 1975; Morris, 1993).

Recent research suggests that this state of affairs is beginning to wane rapidly and that the very stylized models of diffusion of old have receded and been replaced by more complex and powerful representations both in investigation of the spread of diseases (Bauch and Galvani, 2013; Brockman and Helbing, 2013) and in social sciences in general (Homer and Hirsch, 2006).

Centrality of Diffusion in Sociological Theory: Structural vs Diffusion Explanations

Full characterization of diffusion models and theories is of relevance because in social sciences in general, and sociology in particular, researchers seek to empirically identify alternative and competing processes or mechanisms that produce similar observable outcomes.

To fix ideas we introduce a simple but useful distinction between structuralist and diffusion explanations of social phenomena. Although we argue below that the stark opposition between these two is ultimately misleading, social sciences is riddled with controversies pitting one against the other and their contrast is useful to define more precisely the nature of a diffusion approach. Structural explanations of behavioral changes seek their causes in changes of tastes, preferences, and opportunities that result from either shifts in individuals' social positions (social mobility) or from reshuffling of resources associated with these positions (structural social mobility, redistribution of wealth).

Diffusion explanations or models, on the other hand, attempt to identify mechanisms conducive to cumulative adoption of behaviors by some individuals, even while their social positions or the resources associated with them remain unaltered. In diffusion models, the behavior spreads and is adopted by individuals irrespective of their socioeconomic positions, even among those whose objective positions are hypothetically associated with cost-benefit calculations that do not require or are inconsistent with the new behavior. Adopting the new behavior occurs as a result of reevaluation of one's own choices in light of other people's behavior, not as a strategic response or accommodation to a realignment of resources associated with one's social position in the social system. As in models for collective behavior (Coleman, 1990) diffusion models are built on the idea that, individuals transfer partial or total control of their own behavior to others. This implies a decision process that needs to be explicitly modeled: the decision to adopt a behavior is now affected by the actual or perceived adoption by others: the individual behavior object of study becomes endogenous (Manski, 1995).

This conceptualization of a diffusion explanation has the virtue of reintroducing explicitly the role of social interactions, their influence on individuals' calculations, and the potential for spillover effects as the adoption of a behavior may alter the very nature of the social groups and the distribution of individuals' positions within it. Below I provide two illustrations of the clash between structuralist and diffusion explanations, one from political sociology and the other from population history.

Class and Ethnic-Based Politics

Contrary to expectations, class-based political alignments do not always take hold at the same pace as industrialization progresses. Instead, traditional political allegiances, based on language or ethnic identities, could remain dominant long after industrialization creates conditions for class-based politics. This is a well-studied phenomenon in political sociology and is part of the large field of research on nationalism, ethnic enclaves, and the persistence of nonclass-based allegiances and ethnic enclaves (Hechter, 1975; Hechter et al., 2006; Brubaker, 1996). In these cases, observed individual political behavior (voting behavior, for example) is at odds with what is expected by virtue of individuals' ranking in the social system. Failure of individuals to act according to class positions – an expectation derived from a structuralist explanation of political behavior – occurs as a result of adherence to practices consistent with positions occupied prior to the social and economic transformations that accompanied industrialization. What is diffused and adopted in this case is the individual resistance to act according to class-based principles (the new behavior) and the continued allegiance to more primordial social markers.

Fertility Decline

In contrast to predictions from the classic demographic transition theory, fertility decline in Europe did not always follow a trajectory consistent with social and economic transformations that accompanied industrialization. Instead, the course of the decline roughly proceeded along ethnic, language, and religious boundaries (Coale and Watkins, 1986; National Research Council, 2001). The resulting geographic and

territorial clustering of fertility levels and patterns has been construed as evidence against a structural explanation of fertility decline, and as support for the hypothesis that fertility changes were instead associated with ideational or cultural changes and diffusion mechanisms. Clustering of fertility changes along spatial/religious/language that is inconsistent with levels of urbanization or industrialization is prima facie evidence of diffusion of a low fertility norm and/or of knowledge about family size limitation. A similar explanation has been favored to account for post-1950 fertility changes in (most) low income countries, where sharp fertility declines take place suddenly, in a highly contracted period of time, and generally in the complete absence of significant macroeconomic changes, growth, and development (Cleland and Wilson, 1987; Bongaarts and Watkins, 1996).

The examples from political sociology and population theory given above share two features. The first is that in both cases there are two competing explanations: one that infers expected behavior from a reading of individual socioeconomic positions (structuralist) and the second one that infers a pattern of expected behavior from adherence to beliefs shared by others in the same community, including those situated in different position in the social hierarchy. Second, both explanations assume that individuals are decision makers, acting in uncertain environments, sorting through limited information on prices, utilities, constraints, potential outcomes of alternative behaviors, elucidating their own preferences, and ultimately taking some course of action. Yet whereas, as a norm, structuralist accounts consistently include an explicit representation of the individual decision-making process, it is only of recent that diffusion models are built including social influences that affect individuals' decision making. These new formulations of diffusion processes have sprung in many areas, not just in sociology, and have adopted many forms. But they all share one commonality, namely, that the explanation of the outcome of interest as a result of diffusion involves interconnected actors whose decisions may reinforce each other albeit with time lags, and whose relative positions may change as a result of the process itself (Montgomery and Chung, 1994; Montgomery and Casterline, 1993; Valente, 1995, 2010, 2012; Marsden and Friedkin, 1993; Burt, 1987; Granovetter, 1973; Durlauf and Walker, 1998; Brock and Durlauf, 2001; Christakis and Fowler, 2007, 2008; Banerjee et al., 2013; Kossinets and Watts, 2006; Aral and Walker, 2012).

Weak Identification of Diffusion Processes

The bulk of evidence to discriminate between diffusion and structuralist explanations conventionally rested on aggregate data. Since in conventional diffusion models the individual adoption process is poorly, if at all, specified, the aggregate process and its outcome are ill defined: seldom is there a way to determine what kind of aggregate evidence one would expect when the individual adoption process itself is undefined. The last resort is the generalized practice of using 'residual evidence' or, equivalently, to infer the validity of the diffusion model from the weaknesses of the structural explanation, e.g., what the latter cannot account for is assumed to be the outcome of diffusion. This unsatisfactory state of affairs began to recede only recently, perhaps no longer than 20 years ago, when diffusion models were finally coupled systematically with social network theory, when individual decision making involving social interactions were explicitly defined (mostly by economists) and, finally, with the advent of agent-based models, a powerful tool with the capability to generate bounds for estimates of the influence/magnitude of diffusion processes. The nature of these advances is reviewed below.

The Diffusion of Modern Diffusion Models

About two decades or so ago, sociological analyses of diffusion processes began to move away from conventional contagion models and to reintroduce and place complexity of social interactions and individual behavior at the center of diffusion research (Palloni, 2001). The object of study was reshaped and rather than targeting aggregate parameters, such as the overall adoption rate, researchers began to focus on individual processes that led to either adoption or non-adoption of a behavior, the timing of the adoption and, strategically, the effects of the adoption process itself on the structure of the social group. This type of model shifts the focus away from aggregate outcomes toward individual behaviors and individual adoption, and redirects attention toward actors who are decision makers, to the processes of social influence that shape individual decision making, and to the changes in the landscape of prices, constraints, and preferences that the diffusion process itself induces (feedback mechanism). These new models lead to predictions about aggregate trajectories that are a transparent outcome of individuals' actions governed by the diffusion process. These models now enable the researcher to fully incorporate complexities of the adoption process itself (interagent communication, external sources, barriers, agents of change, etc.), the social conditions of interaction between actors who are adopters and potential adopters and, importantly, relevant feedback mechanisms. To evaluate the progress and improvements made in the last two decades we turn to a more rigorous definition of the elements of a diffusion process, including traditional and modern ones.

The Elements of a Diffusion Processes

The new approaches to the study of diffusion include the following elements:

Actors, Decision-Making, and Social Interactions

A diffusion process occurs among individual decision makers that evaluate costs and benefits associated with adoption (or its obverse, resistance to adoption), as well as information and ignorance about prices, costs, outcomes, and alternatives. Unlike other processes, however, individual calculations include the observed, anticipated, or presumed behaviors of other members in the group. The inclusion of the individual capacity of decision making and the intrusion of others' behavior on individual calculus is what distinguishes social from biological evolution (Cavalli-Sforza and Feldman, 1980). The diffusion process involves individual social learning, social influences associated with different individuals in the group,

and institutional constraints (Montgomery and Casterline, 1996; Erbring and Young, 1979; Marsden and Friedkin, 1993; DiMaggio and Powell, 1991).

Social Structure as Context

Adoption of new behaviors occurs within a social structure composed of formal and informal elements. Actors occupy positions in a hierarchy, perform roles, are connected formally and informally to other individuals through relations of authority, functional rapports, respect, and trust. Their positions shape the information they may receive about prices, utilities, and what others are doing, and values and norms determine the repertoire of acceptable and feasible behaviors. Emphasis on the importance of social structure for diffusion processes is hardly new (Rogers and Kincaid, 1980; Coleman et al., 1966; Burt, 1987) but it has seldom been systematically incorporated into actual empirical research on diffusion. It is only recently that sociologists interested in diffusion account for it explicitly in the formulation of models (Valente, 2010; Strang, 1991; Strang and Soule, 1997).

Individual Heterogeneity

Given preferences, prices, budget constraints, and their positions in a social structure, individuals may be more or less resistant to adopt innovations, more or less able or willing to learn from others and, if they adopt at all, more or less reluctant to retain the innovation in the menu of practices and behaviors they normally employ. That is, after one accounts for all standard elements entering in the decision to adopt or to resist, there could be individuals who are more (less) risk averse and adopt more (less) easily than others. Factors that contribute to such variation include social and economic stratification, geographic location, access to communication networks, and heterogeneity in behavioral characteristics that govern both awareness and eventual adoption (Cavalli-Sforza and Feldman, 1980).

Persistence and Reversibility

Once adopted new behaviors could be abandoned and replaced by others. This implies that diffusion models must include components to understand the persistent use of the innovation. This is of particular importance in applications to social behaviors that are inherently reversible or unstable due to changes in the risks involved (for example, participation in mass protests or feedback mechanisms that alter the organization of social groups, the position of individuals within it, or the distribution of resources and opportunities (see below)).

Endogenous Feedback

Both, the individuals' position within the group and the structure of the group, could be modified by the process of adoption itself. This implies the existence of feedbacks that may accelerate or retard the process. This is a key feature of modern approaches to diffusion processes that distinguishes them from more traditional approaches. Although the power that alternative models may have to enable inferences in the operation of feedback mechanisms may differ, they all include explicit consideration of it.

The following are three examples of feedback mechanisms in diffusion processes. In all three of them the spread of a behavior changes the decision-making environment for everybody thus influencing the diffusion process itself.

- Vaccination campaigns and the spread of diseases: the spread of antivaccination campaigns changes the collective exposure to the risk of contracting the disease and this, by itself, may reduce incentives to resist vaccination thus undermining the antivaccination campaign (Bauch and Galvani, 2013).
- Vigilance, sexual behavior, and prevalence of HIV: as the prevalence of HIV increases so does awareness of the disease and willingness to modify sexual behaviors. The spread of new behaviors (through reduction of sexual partners, steadier relations, sexual protection, control of other sexually transmitted diseases) is likely to reduce HIV prevalence and this can weaken the efficacy of collective efforts, public campaigns, awareness, and individual incentives to retain modified behaviors. The outcome may be a renewed increase in the prevalence of the disease (Bauch and Galvani, 2013).
- Adoption of technology: the adoption of some technologies (cell phones, software, and operating systems) becomes unavoidable once a critical mass of users has adopted it since the incentive structures for all users is altered, becomes more favorable for adoption of the new technology, and can even create additional opportunities that reinforce adherence to it.

The combination of these five ingredients produces considerable empirical variability. Diversity in the feedback mechanism alone (strength of endogenous feedback, time lags, threshold effects, number, and complexity of mechanisms on which it is sustained) can lead to aggregate outcomes that vary from runaway adoption and saturation, wholesale abandonment of the new behavior, or oscillations between states characterized by different levels of prevalence of the new behavior. This heterogeneity makes it difficult to infer a mechanism (diffusion vs structural mechanism, different types of diffusion) from observation of limited features of the process, such as its speed or the inflection point(s) of the growth curve of adopters. A more precise identification of the process requires more detailed modeling. This, in turn, can be done using one or a combination of the three new approaches described below.

Social Network Approaches

Although the development of social network theories, models and methods proceeded and will surely continue to proceed independently, one of the most important advances in the growth and development of diffusion models is the establishment of a bridge between the two subdisciplines. Indeed, social network theory becomes integrated as a submodule within diffusion models in a very precise way: actors' decision-making process is assumed to be influenced by their position within one or a subset of social networks in which they are members, by the frequency and type of ties that link them to other actors within those networks, by the position and degree of influence of other actors, by the types of communication between actors in the network, etc. Diffusion models borrow from social network models a conceptualization of the resources that individuals have access to and can use *by virtue of their*

membership in such networks. Valente (1995, 2010, 2012) was one of the first social network theorists to write extensively about the connection between diffusion models and the sophisticated machinery of modern social networks models (Burt, 1987; Watts, 1999; Doreian and Stockman, 1997; Carrington et al., 2005). Although the linkage had already been implemented in extant empirical work (Hedstrom, 1994; Kohler, 1996), it had rarely been formally used in a systematic way as part of diffusion models. The key innovations is that individuals' decisions to adopt a behavior is defined as a function of standard individual characteristics (gender, education, etc.), network-related network individual traits (such as individuals' position within the network) as well as pertinent network properties (type of network, size, density of interaction, etc.). The individual probability to adopt the behavior(s) is now formally represented as a function of these characteristics. Modern applications of diffusion models enhanced with the substance of social network theory and models are making inroads in many areas in social sciences ranging from health studies (Valente, 2010, 2012; Christakis and Fowler, 2007; Brockman and Helbing, 2013; Bauch and Galvani, 2013), addictive behaviors (Christakis and Fowler, 2008), communications and technology (Kossinets and Watts, 2006; Aral and Walker, 2012), and microfinance and developmental economics (Banerjee et al., 2013).
